	John C. Oakes	466
	H. W. King	471
	Robert E. Horton	473
	J. B. T. Colman	476
1357	**THE TWELFTH STREET TRAFFICWAY VIADUCT, KANSAS CITY, MISSOURI.**	
	By **E. E. Howard**	484
	Discussion:	
	By F. W. Green	533
	L. J. Mensch	534
	Howard W. Holmes	541
	M. M. Upson	547
	E. A. Slettum	550
	L. R. Ash	563
	John Lyle Harrington	567
	E. E. Howard	569
1358	**THE AUTOMATIC VOLUMETER.**	
	By **E. G. Hopson**	572
	Discussion:	
	By George W. Booth	590
	E. G. Hopson	590

No.		PAGE
1359	**THE ASTORIA TUNNEL UNDER THE EAST RIVER FOR GAS DISTRIBUTION IN NEW YORK CITY.**	
	By **John Vipond Davies**	594
	Discussion:	
	By F. Lavis	675
	Milton H. Freeman	677
	W. H. Bradley	681
	James F. Sanborn	682
	Edward Wegmann	682
	R. C. Kellogg	684
	W. W. Brush	684
	Thomas H. Wiggin	685
	William Cullen Morris	687
	John Vipond Davies	688
1360	**CONCRETE-LINED OIL-STORAGE RESERVOIRS IN CALIFORNIA: CONSTRUCTION METHODS AND COST DATA.**	
	By **E. D. Cole**	691
	Discussion:	
	By C. P. Bowie	715
	Emile Low	716
	Ralph J. Reed	719
	E. D. Cole	722
1361	**THE ECONOMICAL TOP WIDTH OF NON-OVERFLOW DAMS.**	
	By **William P. Creager**	723
	Discussion:	
	By Orrin L. Brodie	735
	Edward Wegmann	738
	H. L. Coburn	739
1362	**THE CHERRY STREET BRIDGE, TOLEDO, OHIO.**	
	By **Clement E. Chase**	744
	Discussion:	
	By Edward Godfrey	792
	James Ritchie	794
	Clement E. Chase	797
1363	**THE FAILURE AND RIGHTING OF A MILLION-BUSHEL GRAIN ELEVATOR.**	
	By **Alexander Allaire**	799
	Discussion:	
	By David Gutman	833
	W. R. Phillips	834
	E. P. Goodrich	842
1364	**INDUCED CURRENTS OF FLUIDS.**	
	By **F. zur Nedden**	844
	Discussion:	
	By Clemens Herschel	897
	Carl George de Laval	898
	John C. Trautwine, Jr.	911
	F. zur Nedden	912

No.		PAGE
1365	**SECURE SUBWAY SUPPORTS.**	
	By **A. B. Lueder and W. J. R. Wilson**	914
	Discussion:	
	By H. G. MOULTON	939
	RICHARD A. FIESEL	941
	J. H. O'BRIEN	942
	B. C. COLLIER	943
	LAZARUS WHITE	945
	A. B. LUEDER and W. J. R. WILSON	947
1366	**CHEMI-HYDROMETRY AND ITS APPLICATION TO THE PRECISE TESTING OF HYDRO-ELECTRIC GENERATORS.**	
	By **Benjamin F. Groat**	951
	Discussion:	
	By G. BERTRAM KERSHAW	1276
	GEORGE W. FULLER	1276
	W. D. PEASLEE	1277
	W. L. WATERS	1281
	ROBERT E. HORTON	1282
	THOMAS H. WIGGIN	1286
	W. S. RICHMOND	1287
	BENJAMIN F. GROAT	1290
1367	**ADDRESS AT THE ANNUAL CONVENTION, IN PITTSBURGH, PA., JUNE 27TH, 1916.**	
	By **Clemens Herschel**	1306
1368	**COHESION IN EARTH: THE NEED FOR COMPREHENSIVE EXPERIMENTATION TO DETERMINE THE COEFFICIENTS OF COHESION.**	
	By **William Cain**	1315
	Discussion:	
	By CLIFFORD RICHARDSON	1326
	F. W. GREEN	1327
	E. P. GOODRICH	1328
	WILLIAM CAIN	1331
1369	**A STUDY OF THE BEHAVIOR OF RAPID SAND FILTERS SUBJECTED TO THE HIGH-VELOCITY METHOD OF WASHING.**	
	By **Joseph W. Ellms and John S. Gettrust**	1342
	Discussion:	
	By GEORGE W. FULLER	1382
	F. H. STEPHENSON	1383
	E. G. MANAHAN	1383
	GEORGE E. WILLCOMB	1384
	H. MALCOLM PIRNIE	1392
	JOHN H. GREGORY	1411
	F. A. BARBOUR	1411
	GEORGE A. JOHNSON	1421
	JAMES W. ARMSTRONG	1423
	JOSEPH W. ELLMS and JOHN S. GETTRUST	1426

No.		PAGE
1370	**THE EFFECTS OF STRAINING STRUCTURAL STEEL AND WROUGHT IRON.**	
	By **Henry S. Prichard**	1429
	Discussion:	
	By J. A. L. Waddell	1464
	Henry B. Seaman	1466
	C. A. P. Turner	1466
	T. D. Lynch	1467
	James E. Howard	1468
	H. F. Moore	1472
	F. N. Speller	1475
	J. A. McCulloch	1476
	Ernst F. Jonson	1480
	T. E. Stanton	1481
	Henry M. Howe	1482
	A. C. Irwin	1486
	David A. Molitor	1493
	Clement E. Chase	1497
	Henry S. Prichard	1501
1371	**A REVIEW OF THE REPORT OF CAPTAIN ANDREW TALCOTT, CHIEF ENGINEER, MEXICO AND PACIFIC RAILROAD, EASTERN DIVISION, FROM VERA CRUZ TO MEXICO: EXPLORATIONS, SURVEYS, ESTIMATES, 1858.**	
	By **Emile Low**	1543
	Discussion:	
	By T. K. Mathewson	1609
	H. T. Douglas	1609
	W. T. Ingram	1610
	L. Perez Castro	1612
	T. M. R. Talcott	1614
	H. M. Taylor	1618
	Emile Low	1621
1372	**TEMPERATURE STRESSES IN A SERIES OF SPANS.**	
	By **Tresham D. Gregg**	1626
	Discussion:	
	By Charles W. Martin	1642
	Tresham D. Gregg	1642
1373	**THE FLOW OF WATER IN IRRIGATION CHANNELS.**	
	By **George Henry Ellis**	1644
	Discussion:	
	By H. B. Muckleston	1662
	Harold F. Gray	1663
	S. T. Harding	1666
	Allen Hazen	1672
	R. B. Sleight	1674
	W. G. Hoyt	1681
	William S. Aldrich	1683
	M. J. Orbeck, C. N. Ward, and W. O'B. Henderson	1685
	George Henry Ellis	1686

No.		PAGE
1374	**METHOD OF DESIGNING A RECTANGULAR REINFORCED CONCRETE FLAT SLAB, EACH SIDE OF WHICH RESTS ON EITHER RIGID OR YIELDING SUPPORTS.**	
	By **A. C. Janni**	1689
	Discussion:	
	By EDWARD GODFREY	1697
	E. P. GOODRICH	1701
	ERNST F. JONSON	1702
	CHARLES M. MONTGOMERY	1712
	C. A. P. TURNER	1713
	HENRY T. EDDY	1722
	L. J. MENSCH	1731
	CHARLES F. MARSH	1736
	FRANKLIN R. MCMILLAN	1738
	A. C. JANNI	1754
1375	**THE PRESERVATION OF SANDY BEACHES IN THE VICINITY OF NEW YORK CITY.**	
	By **Elliott J. Dent**	1786
	Discussion:	
	By LEWIS M. HAUPT	1806
	CHARLES H. HIGGINS	1809
	ALLEN HOAR	1811
	F. WILLIAM SCHWIERS	1814
	A. W. BUEL	1815
	B. F. CRESSON, JR.	1816
	ELLIOTT J. DENT	1818
1376	**A STUDY OF THE DEPTH OF ANNUAL EVAPORATION FROM LAKE CONCHOS, MEXICO.**	
	By **Edwin Duryea, Jr., and H. L. Haehl**	1829
	Discussion:	
	By T. K. MATHEWSON	1902
	E. F. CHANDLER	1903
	WILLIAM S. POST	1906
	JOHN E. STIRLING THORPE	1918
	CHARLES H. LEE	1921
	ROBERT FOLLANSBEE	1926
	L. R. JORGENSEN	1931
	ADOLPH F. MEYER	1932
	H. HAWGOOD	1946
	CHARLES W. COMSTOCK	1948
	C. E. GRUNSKY	1968
	H. A. WHITNEY	1983
	M. HEGLY	1991
	ROBERT E. HORTON	1994
	J. W. LEDOUX	1998
	EDWIN DURYEA, JR., and H. L. HAEHL	2000
1377	**THE DESIGN OF A DRIFT BARRIER ACROSS WHITE RIVER, NEAR AUBURN, WASHINGTON.**	
	By **H. H. Wolff**	2061
	Discussion:	
	By H. M. CHITTENDEN	2077
	W. J. ROBERTS	2085
1378	**CLASSIFIED LIST OF SUBJECTS OF LIBRARY SEARCHES, JANUARY, 1901, TO NOVEMBER, 1916**	2086

PLATES

PLATE		PAPER	PAGE
I.	Curves Showing Rainfall and Run-Off in the Coast Range from San Francisco to Santa Cruz	1352	115
II.	General Plan, Picaza Bridge	1353	203
III.	Details of Central Span, Picaza Bridge	1353	207
IV.	Picaza Bridge: Details of Main and Intermediate Piers	1353	215
V.	Diagrams Showing Enlargements and Changes in the Pearl Harbor Dry Dock	1354	233
VI.	Pearl Harbor Dry Dock: Sketches Illustrating Methods of Construction Proposed by Civil Engineer Gayler and Mr. Alfred Noble	1354	269
VII.	General Revised Outline Plan, Pearl Harbor Dry Dock	1354	275
VIII.	Stress Diagrams, Revised Plan, Pearl Harbor Dry Dock.	1354	277
IX.	Stress Diagrams, Revised Plan, Pearl Harbor Dry Dock.	1354	279
X.	Pearl Harbor Dry Dock: Diagram Showing Subsoil Conditions and Typical Section in Cribs I and II for First, Second, and Third Failures	1354	309
XI.	Plans Showing Methods of Construction Followed by Contractor and Modifications Proposed, Pearl Harbor Dry Dock	1354	311
XII.	Isometric Drawing of Pearl Harbor Dry Dock in Course of Construction, Method Proposed by F. R. Harris	1354	313
XIII.	Details of Successive Steps in Construction of Pearl Harbor Dry Dock, Method Proposed by F. R. Harris.	1354	315
XIV.	Determination of Pressure Heads in Porous Foundations (Table 1)	1356	423
XV.	Determination of Pressure Heads in Porous Foundations (Table 2)	1356	425
XVI.	General Plan and Elevation, Twelfth Street Trafficway Viaduct, Kansas City, Mo.	1357	487
XVII.	Influence Line Diagrams for Arch Span, Twelfth Street Trafficway Viaduct	1357	501
XVIII.	Twelfth Street Trafficway Viaduct: Typical Details of Columns, Caps, and Bases	1357	503
XIX.	Typical Details of Slabs, Girders and Longitudinal Girders for Both Decks, Twelfth Street Trafficway Viaduct	1357	505
XX.	Details of Piers of Arch Span at Santa Fe Street, Twelfth Street Trafficway Viaduct	1357	507
XXI.	Twelfth Street Trafficway Viaduct: Details of Arch Span.	1357	513
XXII.	Details of Arch Span Reinforcement, and Structural Parts, Twelfth Street Trafficway Viaduct	1357	519
XXIII.	Details of Hand-Rails, Stairways, Light Brackets, etc., Twelfth Street Trafficway Viaduct	1357	525
XXIV.	Geological Sketch Map of Astoria Tunnel Between 132d Street, Bronx, and Winthrop Avenue, Astoria	1359	599

PLATE		PAPER	PAGE
XXV.	Profile of Astoria Tunnel and River Bottom, Between 132d Street, Bronx, and Winthrop Avenue, Astoria..	1359	601
XXVI.	Plans of Heading Advance and Bench Removal, and Profile Showing Principal Bulkheads, etc., Astoria Tunnel..	1359	627
XXVII.	Substructure Diagram, Cherry Street Bridge, Toledo, Ohio, Showing Piers and Foundation Conditions.....	1362	749
XXVIII.	Substructure Diagram, Showing Plan of Piers, Cherry Street Bridge, Toledo, Ohio.....	1362	761
XXIX.	Scherzer Rolling Lift Bridge over Main Channel, Cherry Street Bridge.....	1362	765
XXX.	Cantilever Girders of Scherzer Bascule, Cherry Street Bridge	1362	779
XXXI.	Details of Track Girder, Cherry Street Bridge.....	1362	787
XXXII.	Floor Details, Cherry Street Bridge, Toledo, Ohio.....	1362	789
XXXIII.	Density, Concentration, and Strength of Salt Solutions..	1366	965
XXXIV.	Concentration and Strength of Salt Solutions Between 10° and 30° Centigrade.....	1366	967
XXXV.	Concentration and Strength of Salt Solutions Between 10° and 30° Centigrade.....	1366	969
XXXVI.	Table of Data and Preliminary Computations for the Chemical Calibrations of Iron Calibrator and Salt-Solution Tank.....	1366	1081
XXXVII.	Calibration Scales at Side of Salt-Solution Tank.....	1366	1085
XXXVIII.	Salt-Solution Distributing System.....	1366	1143
XXXIX.	Details of Sampling System.....	1366	1151

XLVIII.	Final Curves. Tests of Unit No. 13. Third Series.....	1366	1221
XLIX.	Final Curves. Tests of Unit No. 12.....	1366	1223
L.	Final Curves. Tests of Unit No. 11.....	1366	1225
LI.	Diagram Showing Performance of an 80-Inch Twin-Runner Allis-Chalmers Turbine Unit.....	1366	1227
LII.	Composite Rating Diagram. True Velocities Determined by Ott Meter No. 2311 and Price Meter No. 1553....	1366	1245
LIII.	Composite Rating Diagram. True Velocities Determined by Ott and Price Meters.....	1366	1253
LIV.	Composite Rating Diagram. True Velocities Determined by Haskell Meter No. 2 and Price Meter No. 1553....	1366	1259
LV.	Composite Rating Diagram. True Velocities Determined by Haskell and Price Meters.....	1366	1261
LVI.	Composite Rating Diagram. True Velocities Determined by Ott and Haskell Meters.....	1366	1263
LVII.	Cost of Grading and Masonry by 1-Mile Sections, Mexico and Pacific Railroad, Eastern Division.....	1371	1571
LVIII.	Railroad Lines Between Vera Cruz and Mexico.....	1371	1625
LIX.	Data on Concrete Channels.....	1373	1657
LX.	Data on Earth Canals.....	1373	1661
LXI.	Coefficient, C, in the Formula, $V = CR^{\frac{1}{2}}S^{\frac{1}{2}}$, for the Flow of Water.....	1373	1687
LXII.	Measured Monthly Evaporations and Corresponding Mean Monthly Temperatures for Stations in Texas and New Mexico (Table 17).....	1376	1863

PLATE		PAPER	PAGE
LXIII.	Curves Showing Relations Between Evaporation and Temperature	1376	1871
LXIV.	Cumulative Evaporation and Temperature at Stations for Which Evaporation was Measured in Texas and New Mexico (Table 21)	1376	1873
LXV.	Diagrams Showing Relations Between Evaporation and Temperature Considered Cumulatively	1376	1875
LXVI.	Measured Evaporations and Temperatures at La Boquilla, Mexico, and El Paso, Tex. (Table 34)	1376	1889
LXVII.	Measured Evaporations and Temperatures at La Boquilla, Mexico, and El Paso, Tex. (Table 36)	1376	1891
LXVIII.	Sketch Map of Great Plateau Region, Showing Principal Weather Bureau Stations and Their Approximate Elevation and Relative Humidity	1376	1945
LXIX.	Isohyetose Map Showing Lines of Equal Yearly Mean Rainfalls in Parts of Northern Mexico	1376	2057
LXX.	Plan of Drift Barrier, The Inter-County River Improvement, near Auburn, Washington	1377	2075

ERRATA

Transactions, Vol. LXXIX.

Page 1435, line 8, for "William Jacomb-Hood", read "William Jacomb".

Transactions, Vol. LXXX.

Page 1495, line 8, insert the words "twice the", before "live-load", making the line read: "shall be proportioned for the algebraic sum of the dead- and twice the live-load".

Page 1496, line 8, for "16.54 sq. in.", read "16.64 sq. in.".

Paper No. 1352

WATER SUPPLY OF THE SAN FRANCISCO-OAKLAND METROPOLITAN DISTRICT*

By H. T. Cory, M. Am. Soc. C. E.

With Discussion by Messrs. F. T. Robson, L. J. Le Conte, C. E. Grunsky, William Schuyler Post, M. M. O'Shaughnessy, Allen Hazen, J. D. Galloway, F. G. Baum, E. G. Hopson, O. W. Peterson, Carl J. Rhodin, Clement H. Miller, Rudolph W. Van Norden, Burton Smith, C. E. Sloan, Edwin Duryea, Jr., H. H. Wadsworth, W. C. Hammatt, A. Griffin, J. Horace McFarland, F. C. Herrmann, Walter Henry Brown, and H. T. Cory.

Synopsis.

This paper deals particularly with the municipal water supplies, present and future, of the cities around the Bay of San Francisco, and incidentally of the so-called Hetch Hetchy project, for which Congress recently granted the necessary permits.

First, a detailed study is made of the population growth of the San Francisco-Oakland Metropolitan District and its several subdivisions. The conclusions reached are that, probably:

The East Bay portions will pass San Francisco proper in population, and to a greater extent in water requirements, in about 20 years;

The next census will show the entire district second to Greater Los Angeles; and that,

* Presented at the meeting of November 4th, 1914.

After a normal growth for two or three decades, Greater San Francisco-Oakland, and especially the East Bay district, will, for a few decades, grow very rapidly.

Then follows a brief description of existing systems and statements of their possible full development.

The question as to whether the Bay cities need and can afford a distant supply in the immediate future is then discussed.

Four or five decades hence, with the utmost co-operation of all interests, local supplies must be supplemented by water brought in from a distance.

The last two parts deal, respectively, with the considerations governing a wise choice of such distant supply or supplies, and the various possibilities.

The conclusions are that the problem is much more, and almost exclusively, one for the East Bay cities, than for San Francisco, and the desirability of considering the situation from this standpoint very carefully, before definitely fixing on the Hetch Hetchy project, is advised.

Introduction.

Urban communities on San Francisco Bay in California have proposed to secure additional water supplies. After more than a decade of endeavor, the City of San Francisco, acting in its own name, but latterly in behalf of a proposed metropolitan water district, has just secured permission to use the Hetch Hetchy Valley and dam site on the main Tuolumne River, within the boundaries of the Yosemite National Park. The privilege of doing this was bitterly contested by numerous individuals, societies, and associations. Widespread interest was aroused, and much feeling engendered.

Because of the interesting nature of the problem to the Profession; because of the many engineering facts which have been brought out from time to time in a multitude of generally inaccessible reports and hearings before Government officials and Congresses; and because various engineers have differed so widely in regard to many matters, a comprehensive paper on the subject is believed to be timely.

Topography of San Francisco Metropolitan Area.—San Francisco Bay, with its outlet to the ocean—the Golden Gate—is about in the middle of the California coast line.

FIG. 1.

The relief map, Fig. 1, shows the immediate region. The Northern Peninsula, generally referred to as Marin County, is quite hilly and mountainous, with a relatively small area suitable for urban development. The Southern Peninsula, on which is the City of San Francisco, has a much more favorable, but still unfortunate, topography for city building. The portion south of the corporate line, and as far as the City of Santa Clara, is locally known as the "Peninsula," only the eastern edge of which is level or relatively so. The mainland along the east shore of the Bay from Richmond south has a comparatively narrow strip of level area, changing to rolling, and then to sharply hilly, country. This increases in width toward the south. The total area suitable for urban development on this side of the Bay is many times greater than that in San Francisco and both peninsulas combined.

The range of mountains running along the California coast line—the Coast Range—really ends in Twin Peaks, within the corporate limits of San Francisco, and begins again just across the Golden Gate, extending thence northward.

East of the Bay, another mountain range, parallel to the Coast Range but higher and wider, extends across the entire region, with a very narrow break, known as Carquinez Straits, through which the combined waters of the Sacramento and San Joaquin Rivers are discharged into San Francisco Bay. In many ways this Mt. Diablo Range is a most important topographical feature of the San Francisco Metropolitan District. It modifies in a striking way the local climatic conditions; stands as a barrier against urban growth eastward; affords productive water-sheds and storage facilities for local water developments; and is a very serious obstacle to be overcome in bringing a water supply to the Bay region from those sections of the Sierra Nevada Mountains directly to the east.

Urban Development.—The Mission of San Francisco was established by the Franciscan Fathers on October 9th, 1776, practically in the geographical center of the present City of San Francisco. In 1846 there was only a little settlement, called Yerba Buena, on the shores of Yerba Buena Cove, between Telegraph Hill and Market Street. The name was changed to San Francisco in 1847. With the discovery of gold in California in 1848, the settlement suddenly

became important. For a few decades the growth was phenomenal and then dropped to about the normal in cities of its size.

It is unfortunate that the original settlement was not on the mainland, as the available area for satisfactory city development on the Southern Peninsula is relatively small, and is sharply restricted by the topography.

Effect of Topography.—The effect of the local topography has been very marked. The disposition of the land masses affects the fog distribution and results in a peculiarly great variation in climatic conditions over the district. San Francisco's climate is foggy and windy, generally speaking, with summer temperatures only slightly higher than those of winter, the thermometer rarely reaching 80° Fahr., and even a few scattering snowflakes and thin films of ice are to be seen only at intervals of years.*

The city is compactly built, due to the limited area which is not on steep hillsides. As the climate is really quite equable, it is unfortunate that home building was not carried out along the same lines as in Los Angeles and all other California cities, namely, to accentuate and take advantage of the famous climate.

In 1874, the area was materially enlarged by the introduction of cable cars, which were developed to meet the local situation. A railroad built into the interior of the State in September, 1869, naturally ended on the east shore of the Bay, with ferry service into the city proper. The suburban service thus available to the mainland, started settlements in Alameda, Oakland, and Berkeley, where ample space, milder climatic conditions, and cheap individual water supplies resulted in a different type of city building.

At first ocean shipping was of pre-eminent importance, and the development was determined by deep-water wharfage. As railway transportation increased in relative importance, commerce was influenced by the railway terminals on the mainland, but the position of San Francisco as the commercial center has become so firmly established that it is doubtful whether it will ever be transferred across the Bay.

Effect of Geographical Location.—In the nature of the case, San Francisco's population is cosmopolitan and self-sufficient. The city very quickly became a metropolis, and was effectually isolated from

* The last snowfall was 1 in., on March 3d, 1896.

any other center. It was the financial and commercial hub of western gold mining enterprise, which attracted the energetic and adventurous from all over the world. There are large foreign quarters in other cities of the country, but in San Francisco—except in Chinatown—the many nationalities are diffused. Consequently, its civic, religious, educational, and political ideas and institutions were and are different from those obtaining anywhere else in the United States. It is financially self-made, self-centered, and self-sufficient. The prevailing spirit was, and in large measure is yet, against San Francisco being a "cheap town." It is a wealthy one. Large personal freedom developed, and precedents of all kinds, including engineering methods, quickly came to be regarded lightly—often with excellent results.

In consequence, individualism was developed to an extreme, with a corresponding lack of co-operation. This condition obtains in a less, but still marked, degree to-day.

Considerable manufacturing necessarily developed, and, until the last decade, little was done on the Pacific Coast outside of the city. It became the center of Labor Unionism on the Coast, more particularly after the successful protests of Dennis Kearney and his followers against Asiatic labor competition.

Limits of Greater San Francisco-Oakland, as Used in This Paper.—The census adopts for metropolitan districts all urban population within 10 miles of the municipal boundaries. In this paper, however, the term will be used as including the territory which, logically, should ultimately have a common water supply. It is practically coincident with the region circumscribed by a circle of 30 miles radius with the San Francisco Ferry Building as the center. Greater Los Angeles, similarly, is considered as the area within a radius of 30 miles from the Los Angeles City Hall.

I.—Probable Future Population.

Growth of San Francisco.—For the past three decades the growth of the San Francisco Metropolitan District has been steady, and at the average rate for American cities of like population, but very much slower than Chicago, New York, and several others, when they were of similar size. The disastrous conflagration following the earthquake of April, 1906, temporarily affected San Francisco proper most seriously, but markedly accelerated the development of the East Bay

cities and other suburbs. Such effect was not great enough to explain the relatively slow growth of Greater San Francisco-Oakland as compared with all other important centers on the Pacific Coast and in the Far West during recent years.

The reasons for this, and how potent they will be in the future, are questions of primal importance. The population, and consequently the water requirements, are the first things to be determined in planning a water supply.

So far as the writer is aware, those who have estimated the future population of the district have not analyzed the peculiar conditions in California. The phenomenal percentages of increase in Los Angeles, Cal., Vancouver, B. C., Seattle, Wash., and other Pacific Coast cities in recent years, have never been taken into account, except by adding a statement that, remembering them, "the curve may be regarded as extremely conservative." This is not very illuminating.

Growth of California.—In the decade, 1900 to 1910, California's population increased 60.1 per cent. The rate for Oregon was 62.7%, Nevada, 93.4%, Idaho, 101.3%, and Washington, 120.4 per cent. The weighted average for these four other States was 95.9%, and for Washington and Oregon—the two other Pacific Coast States—95.8 per cent. The numerical increase was, Washington, 623 867; Oregon, 259 229; or together, 883 116—only 11 382 less than California.

Relative Growth of Northern and Southern California.—On examining detailed figures, it is found that the excessive population increase of the State is not of California generally, but of Southern California, consisting of the seven counties south of the Tehachapi—Ventura, Los Angeles, San Bernardino, Orange, Riverside, San Diego, and Imperial. The growth of population in these seven counties was 154%; in the rest of the State it was only 38%, and in the census San Francisco Metropolitan District but 41 per cent. The curves, Figs. 2 to 10, indicate that, unless something in the nature of widespread calamity or war occurs to change the respective rates of growth, Southern California will, by 1920, comprise more than half the State in all essential respects except area.

There are several reasons why this is surprising. They must in time be effective. These, in the probable order of importance, are:

1.—The natural resources of the State, like its precipitation, increase approximately in direct ratio from south to north. A marked exception, whereby the reverse is true, is the attractiveness of the ocean beaches.

2.—The climatic conditions of Southern California, from a residence point of view, are inferior to those of the central and northern

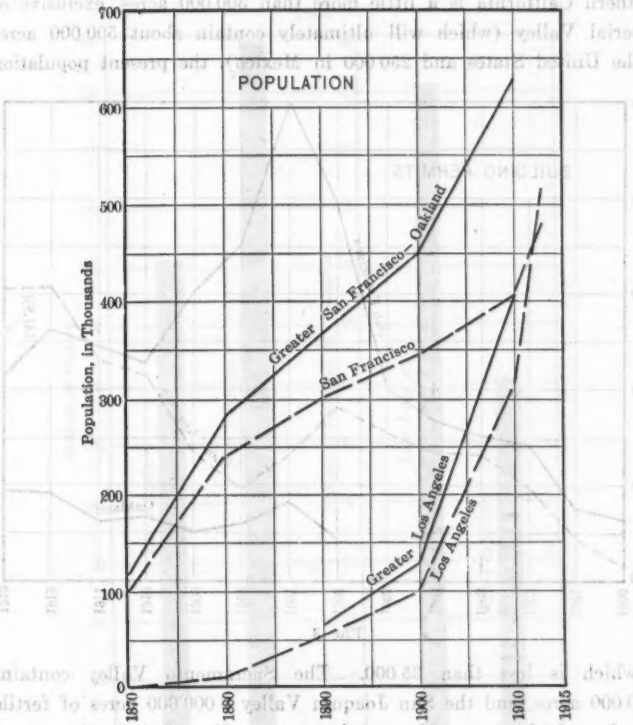

FIG. 2.

parts. This fact has been obscured by the effective advertising of Southern California. Greater San Francisco-Oakland is climatically a markedly better summer resort than Los Angeles, and probably is not equalled anywhere in America.

3.—Within easy reach of San Francisco lies some of the most picturesque scenery in the world. There are opportunities to con-

struct about the Bay cities the most attractive and beautiful roads and boulevards on the Continent, and the Bay is almost unrivaled for yachting and motor boating the year round.

4.—The agricultural and horticultural possibilities of Southern California are literally dwarfed by those of the Central Valley—Sacramento and San Joaquin Valleys—alone. The total irrigated area of Southern California is a little more than 300 000 acres, exclusive of Imperial Valley (which will ultimately contain about 500 000 acres in the United States and 250 000 in Mexico), the present population

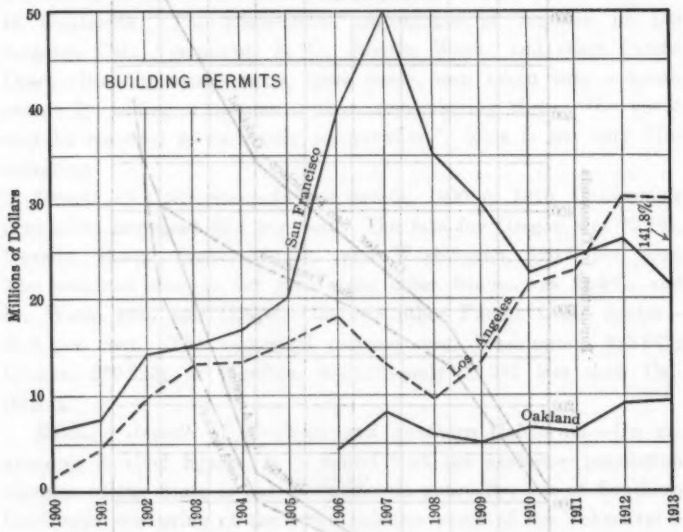

FIG. 3.

of which is less than 35 000. The Sacramento Valley contains 2 250 000 acres, and the San Joaquin Valley 5 000 000 acres of fertile land for which thoroughly satisfactory supplies of irrigation water may be developed at a cost per acre considered low in Southern California. That is, the agricultural development of all Southern California, which was the foundation for its entire development, is only 4% of the easily irrigable area of the Central Valley alone. Furthermore, the proportion of irrigable area adapted to growing oranges, lemons, grape-fruit, etc., is about the same in each region. When it is

remembered that California produces 40% of the world's commercially grown oranges, and that the groves scattered about Sacramento and San Joaquin Valleys have shown that oranges ripen there at least 6 weeks earlier than in Southern California, and suffer less from frosts, some realization of the situation can be obtained.

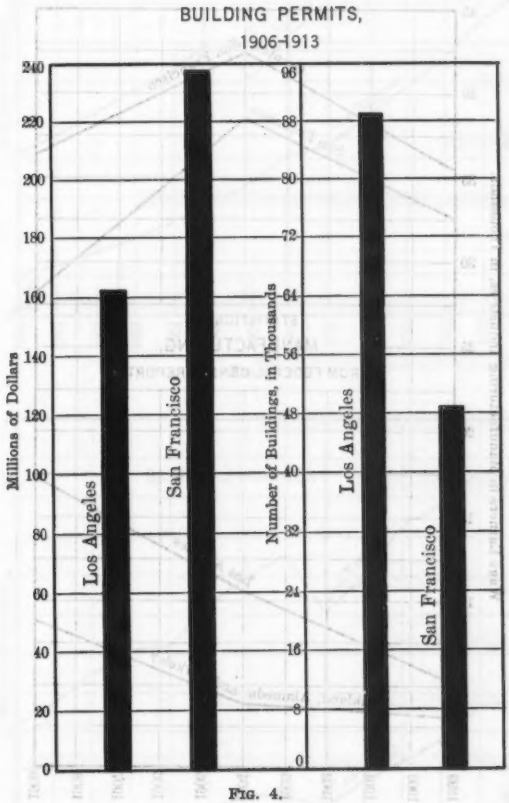

FIG. 4.

The total area of irrigable land logically tributary to San Francisco is 12 500 000 acres, and that of arable land is 15 393 000 acres.

5.—Thirty years ago, when Los Angeles had only 12 000 inhabitants—mostly Mexicans—San Francisco had 250 000, and was the "City" to which people "went down" from a vast region extending

nearly 1 000 miles south, east, and north; it was practically the only seaport on the Pacific Coast, and for more than 10 years was the western terminus of the only transcontinental railway.

In other words, the soil of Southern California is, to say the least, no more fertile; the water supply is by comparison pitifully

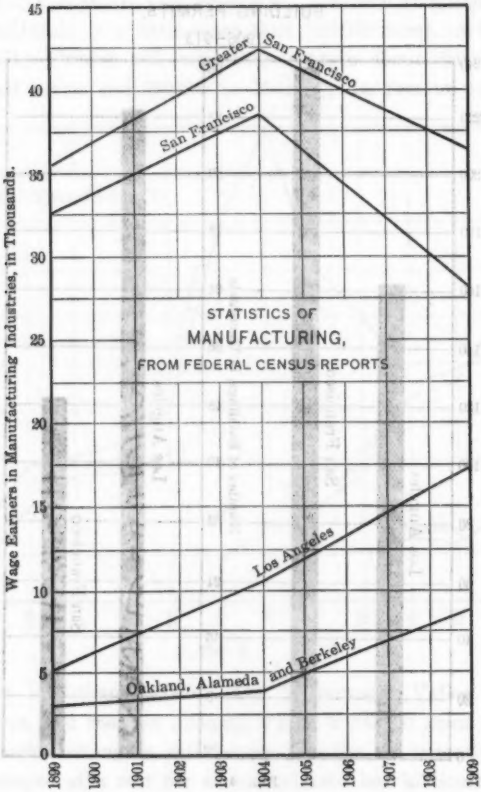

FIG. 5.

deficient; the climate not so delightful nor perfectly adapted to fruit culture, especially oranges and lemons; the extent of back country which can ever be made suitable for intensive farming, but a small fraction of that logically tributary to San Francisco; the natural

harbor and the shipping facilities hopelessly inferior; and the southern country so far behind in population 30 years ago that no one dreamed of real competition.

Under such conditions why should Los Angeles to-day have more inhabitants than San Francisco, with 86% as great an assessed valu-

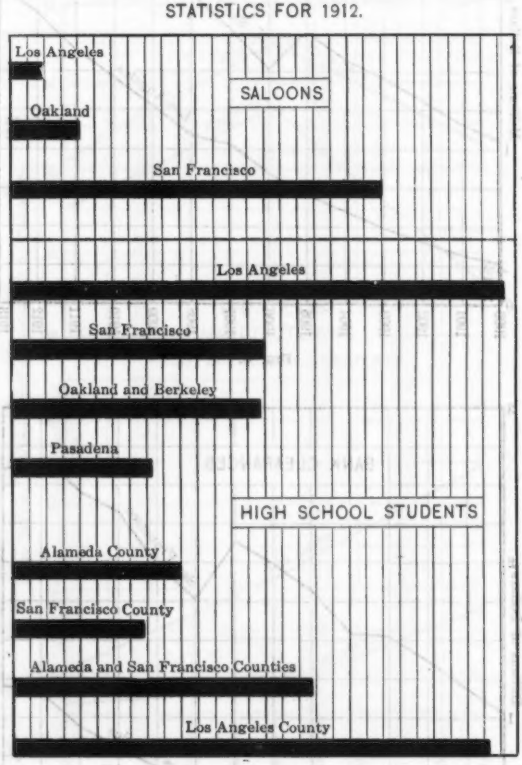

FIG. 8.

ation, and Greater Los Angeles nearly as many people as Greater San Francisco-Oakland, with a similar assessment ratio, and still growing tremendously faster than the northern center?

It seems to be a case of the hare and the tortoise. Natural advantages in the Sacramento and Upper San Joaquin Valleys resulted

in great bonanza grain farms—one man having raised on his own land holdings in a single season 1 000 000 bushels of wheat. It is an agricultural crime to devote such land, with its extraordinary crop adaptation and wonderful climate, to grain culture. In the Southland scanty rainfall compelled irrigation, and irrigation and citrus

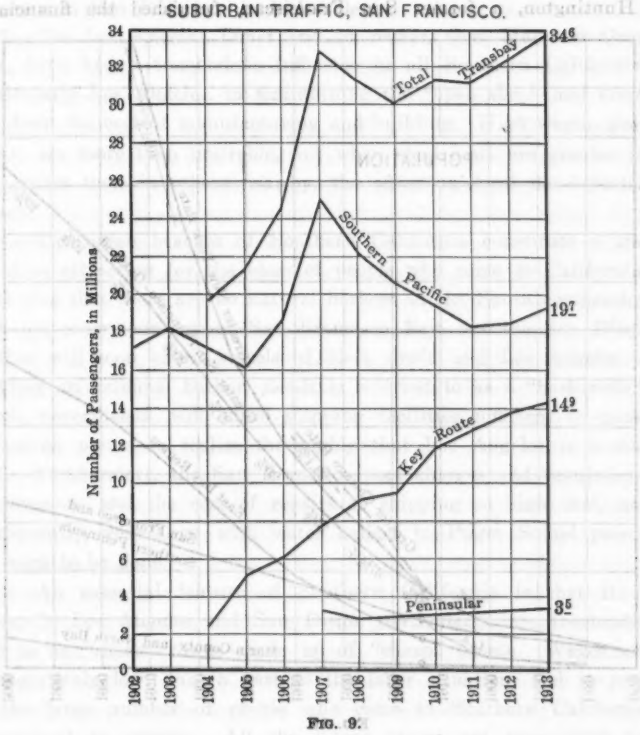

FIG. 9.

culture have been more highly developed there than anywhere else in the entire world.

However, the tremendous advantages of irrigation in the State were fully demonstrated 40 years ago, so that, in addition to this fundamental reason, there must be others quite as potent. These, in the probable order of importance, are:

1.—The Los Angeles Chamber of Commerce. This is doubtless the most efficient organization of its kind in the world, presenting a united, brave front in all matters affecting the development of, not only Los Angeles, but all Southern California. It is doubtless unequalled as an effective advertiser.

2.—The Pacific Electric Interurban System, for which Mr. H. E. Huntington, a former San Franciscan, furnished the financial

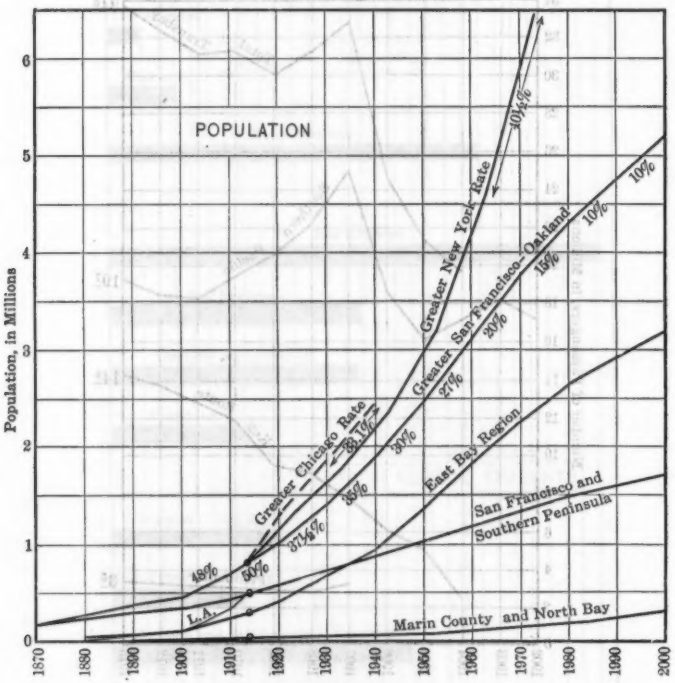

FIG. 10.

strength, and Mr. Epes Randolph, now of Tucson, Ariz., outlined the broad general plans. It is the most complete, extensive, well-constructed, and well-equipped system of interurban electric railroads in the world. There are 6 200 daily train movements over 47 routes, the total number of passengers carried yearly being more than 106 000 000. The total annual trans-bay suburban traffic between San

Francisco and Oakland, Berkeley, etc., is less than 35 000 000, or about one-third, in spite of the fact that such suburban service is, next to that of Los Angeles, the best and cheapest on the Continent.

In addition, there is doubtless no city in the United States—and that means the world—with a system of surface electric roads as modern and well-equipped as Los Angeles. The street railway situation in San Francisco is deplorable.

3.—The *Los Angeles Times* and its owner, Gen. Harrison Gray Otis, have had a tremendous influence in all Southern California, particularly Los Angeles, in maintaining the "open shop" and keeping down the cost of manufacturing and building. High wages, generally, are more than desirable, but when shop costs are greater in one center than in others near-by, the effect on local development is bad.

4.—The ocean beaches of Southern California constitute a tremendous attraction for the class of people who come to California. It is true that there are no natural harbors in the South comparable with the marvelous one of San Francisco Bay, but the San Diego Harbor will soon admit vessels of 35-ft. draft, and Los Angeles is building an artificial harbor, jocularly referred to as a "harborette," which, nevertheless, will afford shipping facilities sufficient to cause competing points to realize thoroughly that Los Angeles is a seaport. Furthermore, the San Francisco port charges and regulations are onerous, and the cost of repairs to shipping so high that, not infrequently, vessels go with water ballast to Puget Sound points for work to be done.

5.—An essential feature of Southern California is that it is "cheap." Los Angeles and San Diego, particularly, are frequently said to be "cheap" towns made up of "cheap" people. Wages are comparatively low, due in part to the labor situation, and in part to the large number of people who come to Southern California determined to remain. All the larger places are surrounded by country topographically suited to indefinite urban expansion in all directions. Consequently, labor and rents are cheap. The expression "Southern Cafeteria," used derisively, has played a very important part.

6.—The fact that Southern Californians are often sneeringly referred to as "goo-goos" (goody-goody) has been an effective adver-

tisement. San Francisco, on the other hand, has been widely advertised as the "Paris of America." There are 200 saloons in Los Angeles and 2 200 in San Francisco proper, and Los Angeles has more than twice as many high school students.

7.—Until a decade ago, San Francisco was, politically, the State of California, and was practically governed by railway interests. Of all boss-ridden commonwealths in the United States, California took first rank, and bribery, "influence," and manipulation of public affairs for the Interests controlling the machine became accepted as a matter of course. The moral fiber of the community was seriously affected. The influx into San Francisco was relatively small, but the tremendous increase in the population of Los Angeles came from all over the United States, bringing a strong strain of Puritanism and higher civic standards. The result for Los Angeles is a community which can and does co-operate and trust its leaders, and secures vastly more advanced civic improvements, of which the water supply is the most striking.

The years of wrangling about San Francisco's water supply and private ownership of the present water system are not accidents, they are only some of the costs of its individualistic temperament.

8.—Because the newcomers quickly outnumbered the natives, Southern California is really not "Western" at all, but a sort of general average of the entire United States and Canada—particularly east of the Rocky Mountains—in education, political and religious ideals, institutions, and spirit. The large cost of railway transportation from New York to the Coast has kept the percentage of European immigration very low. The influx into the State naturally goes to that portion having the same civilization and ideals as the newcomers. Consequently, almost everybody in America has acquaintances, friends, or relatives in Southern California—often very many of them. The result is an "endless chain" never elsewhere equalled.

9.—This factor has been intensified by the limited areas available for intensive cultivation. No large irrigation or colonization schemes were there desirable or even possible. Small, entirely distinct and independent tracts were often settled almost wholly by people from one general community. For example, the Ontario Project, promoted in 1888 and carried to a successful conclusion by

Messrs. William and George Chaffey, formerly of Ontario, Canada, was largely settled by Canadians from that Province, and hence the name. The various settlements—Riverside, Redlands, San Bernardino, Ontario, Pomona, etc.—have retained their individuality. All newcomers have been pouring into small tracts having a gross area of about 300 000 acres, so that the real population density of the inhabited portions of the region is fairly high. The communities have been well established since 1895, and with practically no pioneering work since 1900. So far as municipalities are concerned, however, the reverse is true, in that there are unlimited areas available for urban growth in every direction.

10.—Due to the progressive spirit, the high average and extremely well distributed wealth, and the fact that the country is a tourist playground, automobiling in Southern California is more general than in any part of the world. This quickly resulted in the construction throughout almost the entire region of a system of beautiful boulevards. These have gone far to eliminate what little "pioneering" work was left to be done there a few years ago.

11.—All the scenic attractions of the Southland have been made easy and comfortable of access and brought emphatically to the attention of every tourist. Although the San Francisco Bay region naturally offers much more in every way except ocean bathing, and might be made one of California's greatest scenic assets, this certainly has not yet been done. Thus, Southern California has come to be regarded as the nation's playground and residence section *de luxe*, where the tourist spends his weeks and months while his visit to San Francisco is ordinarily of but a few days *en route*. For this reason it is extremely probable that the Panama-Pacific Exposition in San Francisco in 1915 will really benefit Southern California much more than the Bay region, especially as another peculiarly unique and attractive, though less expensive, Exposition will be held simultaneously in San Diego.

12.—California is in an earthquake region in the sense that *tremblors* are not infrequent. The damage from the shocks of April 18th, 1906, in the East Bay cities was insignificant. In San Francisco proper the chief damage was the breaking of the gas and water pipes in the filled-in areas, thus interrupting the main water supply. This caused one of the disastrous fires of history.

Property worth $350 000 000 was wiped out of existence, many of the inhabitants were widely scattered, and the normal development of the city was violently interrupted. Los Angeles, and to a much less degree, other Coast cities, gained thereby. The final effect on the size of the two cities, however, has been much less than is generally supposed. San Franciscans have nearly all returned. The financial status of many individuals was greatly altered, and the city as a whole is less wealthy than it would have been. Otherwise it, and particularly Greater San Francisco-Oakland, was benefited in many important ways. The effect of the disaster on the location of newcomers to the State was very marked for a time, and doubtless is still appreciable. However, even a great disaster rapidly fades from the world's memory. Los Angeles, quite as much as San Francisco, is in the *tremblor* district, and has fully as many tremors, and by the law of averages the northern city is the safer. Nowhere in the State has a really severe earthquake occurred in historic times; disastrous shocks are like lightning, in that they may strike anywhere. These facts are now generally understood and realized.

Class of Domestic Immigrants.—The people who come to California have not the slightest intention of pioneering, but rather of obtaining the pleasantest home within their means. This is a fundamental fact. That agricultural and suburban land values are from two to five times higher in Southern California than in the Northern sections has not yet had any marked effect, although, of course, it must in time.

It is of the greatest importance to realize that, 20 years ago, when the growth of Southern California began to be really phenomenal—not so much in percentage of population increase as in actual amount and character—the region was agriculturally and horticulturally quite fully developed. There were thrifty, well-matured groves and orchards covering more than two-thirds of the area now devoted to horticulture, with practically all the present steam railway mileage in operation, and beach, park, driveway, and scenic resort development done. In short, all "pioneering" was a thing of the past.

It was then that the future began to be discounted, boosting became general, the Pacific Electric System was built, the oil fields were exploited, and extraordinary growth commenced.

Probable Future Growth Within the State and of Greater San Francisco-Oakland.—To what extent and how quickly may these influences and conditions be expected to change, and with what results?

San Francisco is a big city, and its characteristics will change but slowly. Nevertheless, recently there have been some important forces in addition to those generally in operation. From within there are such people as the Rev. Dr. Aked, Bishops Hughes and Nichols, Jack London, Charles Tenney Jackson, Miriam Michelson, and a number of others, and the great University of California, which has the largest body of undergraduate students in America and strong graduate departments. Those parts of Greater San Francisco-Oakland having less of the Argonaut characteristics are rapidly gaining, and within a couple of decades will outnumber and constantly more deeply influence the main city. From without, the majority vote which the remainder of the State brings to San Francisco has forced woman suffrage, suppression of race-track gambling, throwing off railway political domination, etc. A red-light abatement act would have become a State law a few months ago had not a referendum petition held it up until the November, 1914, election, and San Francisco has already abolished its notorious Barbary Coast. By the initiative, next fall, California will vote on State-wide prohibition.

Thus Greater San Francisco-Oakland is quite rapidly reducing the advantages which Los Angeles urges so strongly, of a "wholesome atmosphere" for family life, although probably two or three decades will be required to secure any degree of parity in this regard between the two great centers.

It will doubtless be a decade before the Chambers of Commerce and Development Boards in Greater San Francisco-Oakland and Central California will speed up to the present Los Angeles standard. It will be at least as long before the present unsatisfactorily financed beginnings of an electric interurban system develop to the Pacific Electric standard, and longer before the natural attractions of the Bay region are fully utilized. The cost of living will probably always be lower in the Southland, and the beach advantages will never be offset, although the counter attractions of the northern Sierra Nevada Mountains will be made more and more important.

With rapidly increasing Far Eastern trade, the great San Fran-

cisco Bay must become an increasingly important factor. The route to the Orient from Puget Sound is more foggy and less safe, and from San Diego and Los Angeles, longer. San Francisco is the logical commercial center—the New York—of the Pacific Coast.

The Panama Canal will have an important effect, but for quite a few years much less than many seem to think. For a number of years other Coast cities will probably benefit almost as much as, if not more than, the Bay cities, particularly with lower manufacturing, handling, and ship repairing costs, due to lower wages and rents.

Within the last 4 or 5 years enormous areas in the great Central Valley have been thoroughly developed, from a land-and-water-company point of view, for sale in small tracts to home builders. The grand total is much more than 1 000 000 acres, equal or superior to, in every regard—except environment and convenience—and held at from one-half to one-fourth the prices of, lands with similar crop adaptation in Southern California. Unfortunately, the general idea has not been to use the land, but to build irrigation works and "colonize." Conditions have changed in the two or three decades since the Southland was developed. In 1880, 70% of the people in the United States were on the soil, to-day but 51 per cent. Subduing and farming irrigated lands is by no means a poor man's business, and in general those who have enough capital to succeed will not pioneer.

Already the large companies see the "handwriting on the wall" and are arranging to prepare, plant, and cultivate the land—develop it completely, and then sell farms and orchards, rather than raw land and agricultural and horticultural problems to individuals. A noteworthy instance is the Mills Orchard Company, which is planting about 10 000 acres of orchards, mostly lemons, at about the midpoint on the west side of the Sacramento Valley.

The State is putting $18 000 000 into a network of permanent highways, and the good roads movement is in full swing in the Central Valley.

Several careful students of conditions in California believe that the State is likely to have a single-tax law within the next decade, especially as the initiative is available. In this event the effect on the lands in question would be tremendous.

Taking all these things into consideration, it would seem that,

in about a decade, the great Central Valley will reach the point where Southern California was 20 years ago, and will develop thereafter in much the same way as the Southland is doing. Also, on account of the increasing tendency to concentrate in large cities, the effect on Greater San Francisco-Oakland will be much the same as the development of the southern country has been on Los Angeles. This in spite of the great extent of back country and the consequent development of relatively large local centers such as Sacramento.

Manufacturing on the Pacific Coast must also increase, but whether faster or slower than the agricultural and horticultural interests depends on several factors. Northern and Central California, Washington, and Oregon, particularly, can and will have more and cheaper hydro-electric power than any other place in the United States, and the rates and service will be, and already are, completely controlled and regulated by utility commissions. California has enormous quantities of fuel oil, but its cost is now equivalent to coal at about $4 per ton, and there is little probability of material reduction. The climatic conditions of San Francisco conduce to the highest labor efficiency on the Continent. The local market is important and rapidly increasing. The Panama Canal will make cheaply accessible enormously greater territory. San Francisco is the nearest point in the United States to the potentially tremendous consuming countries in the Far East.

The present high wage rates and unsatisfactory local labor situation make it unwise to expect very great increase in the near future. Nevertheless, it seems probable that the wage "differential" in favor of the other Far West cities will gradually be eliminated, especially in view of the general tendency toward State and National arbitration of labor disputes, laborers' compensation laws, etc.

It is impossible, of course, to evaluate numerically these many factors, but such is always the case in projecting population curves. Regarding Greater San Francisco-Oakland, it would appear that:

1.—There is no probability of excessive rates of growth for the next 10 or 15 years.

2.—The increase for 1910-1920 will be considerably greater than that for 1900-1910, during which the great fire occurred.

3.—The increase after about 1935 will be very rapid for several decades.

Probable Growth of Various Parts of Greater San Francisco-Oakland.—Of almost equal importance for the matter at hand is the division of the total growth between the main, east-bay, and suburban centers.

The influences resulting in the various local growths have been set forth, chief of which is available area. San Francisco has a population density of more than 10 000 per gross sq. mile, and probably 15 000 per net sq. mile. In Marin County, the area available for city development within a reasonable time zone is relatively small and scattered, so that the suburban traffic facilities are, and, for some time, will probably continue to be, below the other local standards. Nevertheless, the climatic conditions are peculiarly attractive and the region so picturesque as to assure great suburban development of a high grade, with excellent transportation service. The population down the Peninsula will be much denser, but always essentially suburban to San Francisco alone. At the south end of the Bay is San José, as old as San Francisco, about 45 miles from it and from Oakland. It is now, and doubtless for several decades will be, a local center rather than a suburb.

The trans-bay cities, Oakland, Alameda, Berkeley, etc., which are physically one city, were the result of San Francisco's natural barriers, in spite of a suburban trip so onerous as to begin to alienate them when well grown. Another vital factor is the mainland transcontinental, and the most important of the local railway terminals and shops. Fig. 9 shows the trans-bay traffic. After the disaster in April, 1906, very large numbers of San Franciscans went to suburban points for temporary shelter, and gradually came back home in 1908. Since then this factor has been unimportant.

Although the East Bay cities are growing at rates somewhat like that of Southern California, and very much faster than the main city, they are also developing a greater independence and self-sufficiency. The social and political conditions existing in these communities are essentially different from those in the main city.

A bridge from San Francisco to the mainland has often been suggested, in fact a bill is now before Congress authorizing one. The trans-bay traffic indicates that such a structure, or a "tube"—which would be more expensive—is not economically justified, and probably will not be for a long time.

The curves, Fig. 10, show the writer's conclusions from consideration of a great number of elements, chief of which, however, are those just given. All urban population estimates for a period of more than one-third of a century have a sharply limited value. Revolutionary changes, due to inventions, different ideals and tastes—such as a real "back-to-the-soil" movement would typify—cannot be anticipated.

II.—Probable Water Consumption.

Average Daily Consumption Per Capita.—The per capita consumption of water seems to be constantly increasing in all great cities of the United States, and at a somewhat slower rate in most European cities, largely due to higher standards of living. When meters are installed, large water wastes stop, causing an immediate drop in consumption, but an increase at once begins. There is no reason why liberal use should not be encouraged. This necessity and luxury of modern life costs less than any other, when compared with the real comfort it affords. At any rate, the increased consumption in American cities has greatly exceeded the expectations of 20 years ago.

San Francisco has a relatively low per capita consumption, which, in spite of the cool summers, warm winters, and foggy climate, can hardly continue. Wages are high, and people spend freely for comforts. Outside San Francisco proper there will be a marked increase in the use of water for lawns and gardens.

John R. Freeman,* M. Am. Soc. C. E., concludes that the use in Greater San Francisco 50 years hence will be "125 to 150 gallons per capita per day, although by that time substantially every service is metered." The probable curves for all component parts and for the entire Metropolitan District are given in Fig. 11. If anything, the quantity for San Francisco proper is higher in comparison than for the other parts of the district.

Probable Gross Requirements of Greater San Francisco-Oakland and Its Component Areas.—Ordinarily, combining the population and daily per capita consumption curves gives the gross water requirement, but, in semi-humid and arid territories, this is not quite the case. In this district a considerable area is devoted to agricultural purposes, not a little of which will be used in this way,

* "The Hetch Hetchy Water Supply for San Francisco, 1912;" Report by John R. Freeman, San Francisco, July 15th, 1912, p. 79.

even when the population of the district reaches 5 000 000. Until required for city uses, these lands will be cultivated more and more intensively with consequently greater reliance on artificial and controlled watering.

The underground resources made available by wells and the local surface run-off naturally tributary to the region and which can be conserved at a reasonable cost, would be considerably more than sufficient for the arable land. However, much of such water is used in the main and East Bay cities, and it is impossible in considering the water situation of the district to separate the two kinds

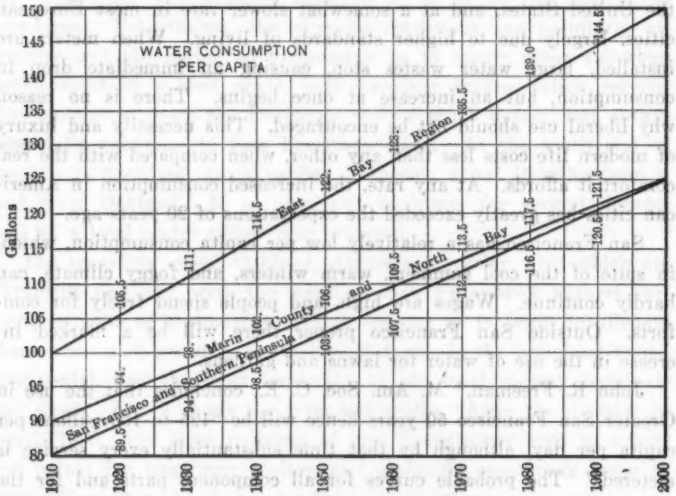

FIG. 11.

of requirements. Consequently, the easy and apparently direct way is ordinarily to obtain the gross water requirement by combining the urban and irrigation uses. Subtracting from these the quantity which may be secured locally, gives the quantity to be brought from a distance.

In doing this, however, it must be borne in mind that well water now available for irrigation and quite satisfactory in quality for domestic purposes will become unsatisfactory for the latter use without effective purification, when the region becomes urban in char-

acter. Hence, it is not correct to assume that the duty of water in residential city areas is, as in Southern California, the same as for horticulture and intensive farming.* Wherever irrigation water is drawn exclusively from very deep water-bearing strata, such fortunate balance may exist, but most of the irrigation water in the district and a great deal of the present East Bay city supply comes from shallow wells.

At present probably 50 000 000 gal. daily, or about 55 000 acre-ft. per annum, are used for irrigation within the district. By the time Greater San Francisco-Oakland has 4 000 000 people, this may be doubled for the area then cultivated, which could hardly exceed from 75 000 to 80 000 acres with croppings requiring about 1½ acre-ft. gross, per annum, in dryer years. Of this acreage, at least one-third would probably be watered from wells, and the remainder of the supply, say, 67 000 000 gal. daily, would be taken from the municipal water district system.† On this assumption the curves on Fig. 12 are drawn.

The grand total consumption curves are derived by adding the supplies for urban and agricultural uses.

III.—Existing Water-Supply Systems.

There are 50 water systems in Greater San Francisco; 20 in the South Peninsula, of which 8 are municipally owned; 12 in the East Bay Region, 4 being municipally owned; and 20 in the North Peninsula and Coast, of which 2 are publicly owned.

San Francisco Proper and South Peninsula.—On the South Peninsula, all but two are relatively unimportant: The municipal high-pressure fire system and the privately owned Spring Valley Water Company of San Francisco. The fire system, completed in 1913 at a cost of $5 200 000, is said to be the most modern and efficient ever built, and protects 8.25 sq. miles.‡ Special precautions were taken to make it as nearly earthquake-proof as possible. Salt water is used only in emergencies and by the two fire-boats on the water-front.

The Spring Valley Water Company has the largest privately owned system of its kind in the world. Fortunately, from a construc-

* This was first pointed out by William Mulholland, M. Am. Soc. C. E., in connection with the estimated water requirement of the City of Los Angeles, when the Los Angeles Aqueduct was under consideration. Practically none of the territory marked out for the future development of Los Angeles secured irrigation water from shallow wells.

† C. D. Marx, M. Am. Soc. C. E., adopts 95 000 000 gal. daily for a much greater district, including a considerable part of Santa Clara County.

‡ The City and County of San Francisco has a total land area of 47 sq. miles.

tion point of view, all planning and building for a period of 43 years ending in 1911, were under one man, Hermann F. A. Schussler, M. Am. Soc. C. E. It was his rule to project his work in considerable detail for 10 years, and, true to his German technical training, he was never satisfied with "good enough work."

Distribution systems in all cities are piecemeal growths. Present conditions, such as sky-scraper construction, were not foreseen. In general, considerably different plants would be installed to-day. Due to the relief afforded by the municipal high-pressure fire system, the high class of construction, and the consistent policy of Mr. Schussler, the distribution system in San Francisco is doubtless the best, with the possible exception of Omaha, Nebr., of any important city in America, so far as it goes. Because of litigation over rates, begun in 1903, very little extension into newer districts has been made. The estimated cost of all desirable work, including extensions, up to 1920 is $2 500 000.

The company collects water from adjoining mountainous areas on both sides of the Bay, as shown in Fig. 1, and distributes 95% thereof in San Francisco proper. The quality is excellent, better than that of any city of half its size in the United States, except as to hardness. This is now about the same as the water of Washington, Chicago, Cleveland, and Louisville, and less than the Owens River supply, to be brought in by the Los Angeles Aqueduct. It will become less as the proportion obtained from surface sources increases. It will be difficult for engineers of the East and Middle West to believe that all present surface supplies come from watersheds having but 18 inhabitants exclusive of employees of the company. The company has carried water-shed protection farther than has ever been even considered east of the Rockies, purchasing outright more than 100 000 acres of water-shed land.

The present daily consumption on the South Peninsula is about as follows:

San Francisco:*	
Spring Valley Company	40 000 000 gal.
San Mateo County	16 000 000 "
Part of Santa Clara County	10 000 000 "
	66 000 000 gal.

* In addition wells and Bay supplies are used in manufacturing, to an unknown extent.

East Bay Region.—On the mainland, the important factor is the Peoples Water Company, which supplies practically all the water used in Oakland, Alameda, Berkeley, and several smaller places. Unlike the Spring Valley Water Company, it is the successor of nine lesser companies which entered the field during the past 45 years. These companies, becoming unable to meet the rapidly increasing demand, were successively displaced by stronger ones. According to J. H. Dockweiler, M. Am. Soc. C. E., who has been Consulting Engineer for the Cities of Oakland and Berkeley for a number of years, the history of these attempts to keep pace with the widely scattered and rapidly growing population centers by private capital is a most interesting and curious succession of failures properly to grasp opportunities and protect investments by adequate preparation for the future. According to him, largely as a result of 5 years' relentless and wasteful competition between two such companies, the distribution properties are in a considerable degree superimposed on each other; short-lived materials have been used extensively, and the mains and reservoirs are out of consistent relationship with the topography of the territory and the developed sources of supply. According to his records, 48% of the nearly 900 miles of pipe are 2-in. and less, and only about 30% are of cast iron. The area served is 67 sq. miles, 27 of which are above the 200-ft. contour, and it is divided into sixteen pressure zones or areas, ranging from sea level to 1 000 ft. elevation. The system has 60 000 connections, 95% of which are metered, relatively few fire hydrants, and average receipts of 25 cents per 1 000 gal., with base rates as high as 35 cents.

About 100 blocks of the business section of Oakland are covered by a municipal fire system costing, to date, $136 000. Elsewhere on the mainland the fire protection is, in general, very poor, and in many areas negligible. The situation in this regard is probably as unfortunate as in any important center in America.

About one-third the water comes from the surface supplies of the company, shown in Fig. 1, and almost all the remainder from wells near the Bay shore. According to Mr. Dockweiler, the quality is generally satisfactory, although hardly up to the standard of that supplied to San Francisco. The present daily consumption is:

Peoples Water Company:	
Surface	7 000 000 gal.
Underground	11 000 000 "
Union Water Company	700 000 "
Other systems	3 000 000 "
Private wells, about 4 000	8 000 000 "
	29 700 000 gal.

This is exclusive of irrigation water.

Marin County and North Bay Region.—The four principal systems are the Marin Water and Power Company, the North Coast Water Company, the Vallejo Municipal Water-Works, and the Benicia Water Company, the latter being privately owned. The first two are supplying about 2 000 000 gal. daily from surface sources, and the others furnish water for Vallejo (population, 15 000) and Benicia (population, 3 000).

IV.—Maximum Safe Yields of Existing Sources.

The maximum safe yields obtainable by the complete economical exploitation of the various local developed and undeveloped sources are about as follows:

San Francisco and Peninsula.—The complete development of the Spring Valley Water Company's sources of supply would require creating the Calaveras Reservoir, by building a dam 220 ft. high, work on which is now in progress; two other reservoirs, San Antonio and Arroyo Valle, all in the Alameda Creek water-shed; and the diversion of other Coast streams into the Peninsula reservoir system.

The Calaveras Reservoir, estimated cost, $1 500 000, will have a capacity of 53 000 000 000 gal., or 162 700 acre-ft. The flow-line elevation will be 790 ft., and the contributory water-shed is 100 sq. miles, or with the Upper Alameda water-shed, 140 sq. miles.

The San Antonio Reservoir, estimated cost, about $750 000, will have a capacity of 11 500 000 000 gal., or 35 300 acre-ft. The flow-line elevation will be 455 ft., and the contributory water-shed, 38.7 sq. miles.

The Arroyo Valle Reservoir, partly storage and partly regulating, is estimated to cost about $800 000, and to have a capacity of 13 000 000 000 gal., or 39 900 acre-ft. Its flow-line elevation will be 800 ft.. and the

contributory water-shed, 140 sq. miles. It is estimated that the related development of underground sources in Pleasanton Valley and at Sunol will cost $1 300 000.

The Peninsula development will intercept the run-off from 65 sq. miles of territory, contributory to Pescadero and San Gregorio creeks, and convey it by canals, pumps, and tunnels into the Crystal Springs Reservoir, at an estimated cost of $8 500 000 for 50 000 000 gal. daily, or $170 000 per 1 000 000 gal. daily.

The maximum yield which could thus be economically secured for use in San Francisco proper has lately been the source of much bitter controversy. Since 1910 an extraordinary number of engineers, usually believed to be especially competent in such matters, have made examinations and have reported widely differing results, as indicated in Table 1.

There are complete records of gauge heights and draft on reservoirs as follows:

Crystal Springs	1888 to date.
San Andreas	1870 " "
Pilarcitos (Except totals only for 1889 and 1898-1902)	1867 " "
Lake Merced (With several breaks prior to 1906)	1883 " "

There are run-off and discharge records as follows:

Niles Dam	1888 to 1900.
Sunol Dam	1900 to date.
Sunol Aqueduct at Brightside Weir	1906 " "
Pumping records at Belmont Station (With some breaks prior to 1898)	1888 " "
Calaveras Creek at dam site	1898 to 1908, and 1911 to date.

Fig. 13 shows the continued run-off data at the Crystal Springs, San Andreas, and Pilarcitos Reservoirs, platted on arithmetic-probability scales, according to the method proposed by Allen Hazen, M. Am. Soc. C. E.* The consistency of the data thus shown makes striking the wide variation of engineers' estimates in Table 1.

* Pilarcitos, San Andreas, and Crystal Springs. † Including Lake Merced. ‡ 25 000 000 000 gal. storage. § Includes Coast streams connected with enlarged (Lower) Crystal Springs Reservoir and also surplus from Calaveras, but does not include San Antonio, Arroyo Valle, Pleasanton, or Sunol gravels.

The territory from Greater San Francisco's southern limits on both sides of the Bay to the south end of the Santa Clara Valley can be fully supplied from the remaining local surface and underground water sources within reasonable limits of cost. There will be little excess, however.

East Bay Region.—The maximum safe yield of underground sources is problematical; it depends primarily on the extent to which the various fruitful underlying water strata are supplied from local sources, such as delta fans and cones, and from distant exposed Pleistocene gravels. Considerable difference of opinion exists regarding this matter, also. Definite conclusions are not yet justifiable as to the extent to which the present draft of probably 12 000 000 or 13 000 000 gal. daily may be safely maintained or increased.

The Peoples Water Company proposes to increase the local surface water supplies by building three dams on San Pablo, Upper San Leandro, and Pinole Creeks, thus creating three collecting and storage reservoirs.

The first of these it is estimated will cost about $2 335 000, have a capacity of 6 000 000 000 gal., or 18 420 acre-ft., and a flow-line elevation of 325 ft. The water-shed is 34.65 sq. miles and the estimated safe yield 8 000 000 gal. per day.

The second reservoir, on San Leandro Creek, estimated cost $2 878 000, would have a capacity of 16 700 000 000 gal., or 51 270 acre-ft., and a flow line at an elevation of 470 ft. The water-shed is 32.94 sq. miles. Below it is the present Lake Chabot or San Leandro Reservoir from which more water is wasted than impounded in seasons of average precipitation. The upper reservoir would conserve all the run-off, and thus increase the safe daily draft about 10 000 000 gal.

The third, on Pinole Creek, the last which would be created, would cost about $676 000, have a capacity of 2 300 000 000 gal., or 7 060 acre-ft., and a flow line at an elevation of 290 ft. The water-shed is 10.5 sq. miles, and the safe draft would be about 3 000 000 gal. daily.

These proposed reservoirs are practically contiguous to built-up areas. In time their water-sheds will be built on; at least, it is desirable that the area be available for the rapid growth of population. It would be necessary to filter the water carefully. The utilization of the San Pablo and Pinole sites would affect the annual water replen-

ishment in the delta cones of these creeks where a considerable number of wells are in use. The quantity of water required to be delivered to such regions as recompense, would be about 1 500 000 gal. daily.

The Richmond Water District plans are for a distant supply from the Sacramento River.

Marin County and North Bay Region.—The plans outlined by the Marin Municipal Water District provide for a total safe draft from local sources of 14 000 000 gal. daily, which is regarded as the maximum feasible limit. In the North Bay region the available increase from local water sources is relatively insignificant.

Summary.—The total ultimate safe draft for municipal purposes, of a quality quite satisfactory and well above the present standards for important cities in America, and obtainable at a reasonable cost by complete development of local sources is, then, about as follows:

For San Francisco and Peninsula	180 to 200
" East Bay Region	37 to 40
" Marin County and North Bay Region	14 to 16
	231 to 256

V.—Can Greater San Francisco-Oakland Afford a Sierra Supply?

San Francisco proper has available a disproportionately large part of the local water yield. By complete development, which can be done piecemeal as necessary, it can have an ample supply of excellent quality for at least 75 years to come, exceptionally large local reservoir capacity, and consequently relatively small upkeep and danger of interruption from floods, landslides, or earthquakes.

The city's present assessed valuation is $623 000 000. To acquire the Water Company's properties needed will cost between $35 000 000 and $40 000 000. The city has not finished rebuilding following a $350 000 000 fire. It has a total authorized bond issue of $43 000 000, exclusive of the Hetch Hetchy issue of $45 000 000 which latter is authorized, but not put out. Because of an exceedingly bad transportation situation, it is well started on a programme of taking over and operating all traction lines within its limits. This will require an estimated expenditure of between $100 000 000 and $125 000 000 during the next 25 years. It has no elevated or subway systems, though these are needed and cannot long be postponed. It is a rapidly growing city, with

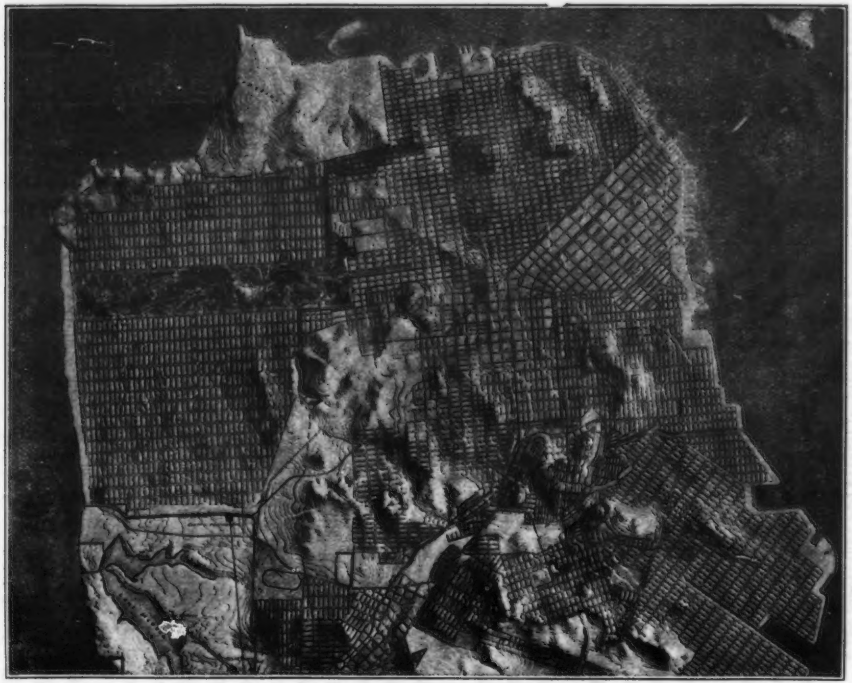

FIG. 14.—RELIEF MAP OF SAN FRANCISCO, SHOWING STREET LINES IN RELATION TO TOPOGRAPHY.

all the financial needs that this implies, yet is already surpassed in population by Los Angeles, which, 15 years ago, was not even admitted to be a rival. Its topography necessitates heavier costs for improvements than in almost any other city in America, and more to be done.* The local labor and political situation makes labor costs high. The temperament of its people makes concerted action difficult and progression slow and along indirect and expensive lines.

The outstanding indebtedness of Los Angeles is about 4% greater than that of San Francisco, with about seven-eighths the assessed valuation. However, Los Angeles owns its local water system, and has finished bringing in the Sierra supply. San Francisco, at least, will have to double its outstanding bond issue, in order to acquire the Spring Valley Water Company's properties, and the proposed completed Hetch Hetchy supply will add more than twice as much. At the best, then, to put the two centers on a proper basis of comparison, including the Sierra supply, San Francisco's bonded indebtedness would be more than four times that of Los Angeles. As to ability to care for such indebtedness in the future, Los Angeles is, in this regard, as in population, growing tremendously faster.

Under such circumstances, the real question is: Can San Francisco afford the luxury of a Sierra water supply at an immediate expense of more than 10% and a total ultimate cost of at least 16% of its present assessed valuation?

San Francisco's natural destiny as the commercial center of the Pacific Coast is beginning to be threatened. At least, until this matter is settled one way or another, San Francisco proper will be the largest and richest portion, and the natural leader of the Bay communities in this struggle.

In competition for newcomers, and in other elements causing a city's growth, is the water supply, as long as it is well above the American standard in quality and is delivered in ample quantities, at reasonable cost, and under satisfactory pressures, an aggressive and

* The topography and natural features of San Francisco are such that it could have been made one of the most beautiful cities in the world. Unfortunately, like many other places, it grew "Topsy fashion," and the layout is rectangular, quite regardless of the configuration of the land. There result grades as high as 22 per cent. The opportunity which the great fire of 1906 presented for re-designing the most important part of the city was not utilized. The City Engineer's office recently stated that $26 000 000 was the cost of certain improvements, necessary under the circumstances, but which would have been entirely avoided had the city's planning been adjusted to the topography, as might have been done, and that this expenditure was but the beginning of a series which from time to time must be made.

obvious factor, as compared with local transportation facilities, modern marine and railway terminals, paving, parks, boulevards, speedways, making areas spoiled by local development available for higher classes of city building, etc.?

Los Angeles, with 86% of the assessed valuation, as a matter of absolute necessity, has brought in a supply of 250 000 000 gal. per day from the Owens River at a cost of a little more than one-fourth of San Francisco's present programme. The quality of this water will, at best, be no better than the local supplies of San Francisco. Perhaps most important of all, however, is the fact that from the very outset, every drop of the water brought in will be used, and at prices well above the existing sinking fund and operation charges per million gallons daily. The reason that this is possible in Los Angeles, and utterly impossible as to Greater San Francisco-Oakland, is that irrigation is absolutely essential in the environs of the southern city, and irrigation water even at the city base rate of 9 cents per 1 000 gal., would be only $29 per acre-ft., which is well within the commercially feasible limit in that territory; on the other hand, in the environs of San Francisco-Oakland, little water is imperatively required, and none could be sold at even $5 per acre-ft. The fact that irrigation requirements for lands adjoining Los Angeles are practically the same as the urban needs will be when the city spreads out over them, has already been mentioned.

If engineering is attaining the best results for the expenditures, this question is an engineering one of the highest type. It is the proper valuation, for a great city's purposes, of two sources of water supply.

East Bay Region.—The situation of the mainland cities is entirely different. The maximum possible development of the local water sources available would supply them for 10, or, at most, 15 years. Their distribution system, according to Mr. Dockweiler, is more than unsatisfactory, and their growth is already seriously hampered by the water situation. It would be advantageous for them, were San Francisco proper to "pull their chestnuts out of the fire." The rivalry between them and San Francisco is such that the latter would doubtless do nothing of the kind were the matter generally thus understood.

These communities face a serious situation. Their combined assessed valuation is only about $250 000 000. The ideal move would be for each section of Greater San Francisco-Oakland to acquire its

respective water system, extend and rebuild its distribution system, as the case may be, pool the local water supplies, and join in bringing in a common distant supply when necessary. Unfortunately, the local political and social situation makes such an arrangement improbable.

It is essential to realize that the water problem of Greater San Francisco-Oakland is very much more one for the mainland cities, than for San Francisco proper.

Marin County and North Bay Region.—What has been said of the East Bay cities is true of Marin County and the North Bay region, except on a much smaller scale.

VI.—Efforts Toward Municipal Ownership.

San Francisco, Oakland, and Denver are the only large cities in the United States which do not own and operate their water-works. According to present California laws, rates, extensions, financing, and service of all public utilities, outside of incorporated municipalities, are regulated by the State Railroad Commission. In November, 1914, the State will vote on the proposal to put all public utilities under the exclusive control of the Railroad Commission, and it is generally believed the change will be made.

Since 1880 municipal councils or supervisors have regulated, practically as to rates only, their public utilities. As elsewhere, this has been unsatisfactory, and at various times more or less serious steps have been taken to acquire or construct local municipal water systems.

San Francisco Proper.—The City had reports made by the late Gen. B. S. Alexander, Corps of Engineers, U. S. A., and the late George Davidson, Hon. M. Am. Soc. C. E., then of the U. S. Geodetic Survey, jointly (December, 1871); the late T. R. Scowden, M. Am. Soc. C. E. (May, 1874); and the late G. H. Mendell, M. Am. Soc. C. E., Col., Corps of Engineers, U. S. A. (1876-77). After the Mendell report the City officials tentatively offered $11 000 000 for the Spring Valley Water-Works' properties on the peninsula and the Company asked $12 500 000. The negotiations were dropped at this point.

On January 8th, 1900, a new charter went into effect, in which was declared the purpose of gradually acquiring the City's public utilities. Under it, the City Engineer at that time, C. E. Grunsky, M. Am. Soc. C. E., prepared plans for an entirely independent system, taking water from the Tuolumne River in the Sierra Nevada Moun-

tains, generally known as the Hetch Hetchy project. He estimated the cost of bringing 60 000 000 gal. per day to the Bay at $31 603 330, and the distribution system at $8 807 000. After 12 years of effort on the part of the City, the necessary rights of way, under severe restrictions, have recently (December, 1913) been granted by Congress in the passage of the so-called Raker Bill. On January 5th, 1914, the City officially accepted the grant and the conditions it carries.

In 1909 the voters passed on an alternative proposition for a bond issue of $45 000 000 to build the Hetch Hetchy project, including a distribution system, or an issue of $65 000 000 to bring in Hetch Hetchy water and buy the Spring Valley Water Company properties for $35 000 000. The latter lacked about 1 100 votes of the necessary two-thirds majority, and the former was carried.

On May 11th, 1908, the Secretary of the Interior at that time, the Hon. James R. Garfield, issued what is known as the "Garfield Permit," granting the rights of way requested by the City in the Yosemite National Park. This required the development of other portions of the project before utilizing the Hetch Hetchy Valley, a wonderful canyon of rugged beauty second only to the Yosemite Valley. On account of many protests, Secretary Ballinger, in March, 1909, acting on the advice of a committee consisting of Dr. George Otis Smith, Director of the U. S. Geological Survey, and L. C. Hill and E. G. Hopson, Members, Am. Soc. C. E., Supervising Engineers of the U. S. Reclamation Service, ordered the City to show cause why the Hetch Hetchy Valley should not be eliminated from the permit. A board of Army Engineers was appointed by President Taft, to assist and advise the Secretary in the matter. The members were Col. John Biddle, Lieut.-Col. Harry Taylor, and Col. Spencer Cosby, Members, Am. Soc. C. E. The appointment of this Board was probably due to President Taft's well-known penchant for the Army. Doubtless, none of these military engineers would urge his qualifications by training or experience as an expert in irrigation, hydroelectric, or municipal water supply matters.

At the request of the City Engineer, Marsden Manson, M. Am. Soc. C. E., Mr. John R. Freeman was called in by San Francisco to assist it in presenting its case. He associated with him eleven other members of the Society and President J. C. Branner of Stanford Uni-

versity. Afterward, M. M. O'Shaughnessy, M. Am. Soc. C. E., succeeded Mr. Manson (September, 1913), and shouldered much of the responsibility. Mr. Freeman fundamentally changed the Hetch Hetchy project as theretofore outlined.

The hearing was held by the Secretary of the Interior, the Hon. W. L. Fisher, on November 25th to 30th, 1912, and it is greatly to be regretted that the proceedings have not yet been published. The Army Board presented a report, largely the work of H. H. Wadsworth, M. Am. Soc. C. E., Assistant Engineer, Rivers and Harbors Branch, Corps of Engineers, U. S. A., on February 19th, 1913. On March 1st, Secretary Fisher decided that he was not authorized to act, and recommended Congressional action. His successor, Secretary F. K. Lane, concurred in this. Hence, there followed the introduction and passage of the Raker Bill.

On December 31st, 1913, the City of San Francisco filed suit to condemn the properties of the Spring Valley Water Company. A year before, tentative negotiations had been broken off, with the Company asking $37 500 000 and the City offering $37 000 000.

East Bay Cities.—On the mainland, Oakland and Richmond are the only communities which have made definite efforts to acquire water systems and supplies.

Oakland.—In 1902 Rudolph Hering, M. Am. Soc. C. E., made a report for a Citizens' Committee on the water supply for Oakland. He advised that 15 000 000 gal. per day of underground water could be obtained from the delta cones of Alameda Creek. In 1903, Desmond FitzGerald, Past-President, Am. Soc. C. E., reported to the same committee, and the next year a Board of Engineers, consisting of A. M. Hunt and J. M. Howells, Members, Am. Soc. C. E., and Mr. F. C. Turner, reported to the Oakland authorities on the adequacy of the Bay Cities Water Company's project for a local surface water supply from near Mt. Hamilton. A bond issue for taking over and building this project was defeated by the voters in December, 1904.

In the same year the rates of the Contra Costa Water Company (since absorbed by the Peoples Water Company), in Oakland, were fixed by the City authorities at a point so low that the Company appealed to the Courts. The result was the same as in San Francisco, namely, expensive litigation still pending and inadequate extensions of the system.

In 1910 litigation was begun between the Peoples Water Company and the City of Berkeley, but it was soon compromised by minor concessions on the part of the Company.

The formation of a municipal water district is now being considered.

The Richmond Municipal Water District.—This district was formed by an election held December 3d, 1912, covering the region bounded on the south by the Alameda-Contra Costa County Line and on the east and north by an irregular line approximating the eastern edge of the San Pablo Creek water-shed. It contains 56 sq. miles, of which 40 sq. miles are below the 200-ft. contour. The population on June 30th, 1913, was estimated at 15 585, of which 13 575 were in the City of Richmond. The present assessed value in the district is $19 400 000.

The present daily water consumption is 3 400 000 gal., equal to 194 gal. daily per capita, of which 123 gal. are used in manufacturing and industrial pursuits. All water is pumped from underground sources, and almost exactly one-half is from private wells, the draft from which has about reached the available limit. The future per capita use will probably increase to 230, and then gradually drop to 150 gal. per day when the population reaches 150 000. Such large per capita consumption is expected because the industrial growth for many years will exceed the residence and business increase. There is no adequate fire protection.

The engineers of the district, Mr. P. A. Haviland, M. Dozier, Jr., M. Am. Soc. C. E., and F. H. Tibbetts, Assoc. M. Am. Soc. C. E., of San Francisco, have reported exhaustively on two water sources available. These are, a reservoir on San Pablo Creek,* and by pumping from the Sacramento River at Toland's Landing, with an emergency intake at Antioch. The safe draft of 12 000 000 gal. daily can be secured from San Pablo Creek at a cost of about $3 500 000, and a like quantity brought from the Sacramento River, including a mechanical filtration plant, for from $4 000 000 to $5 600 000, depending on the conduit route and the materials used. The immediate development of a filtered river supply for 6 000 000 gal. daily, at a cost of from $2 300 000 to $4 100 000, depending on location and construction details desired, was recommended. The District's

* This reservoir site is the one already mentioned as being owned by the Peoples Water Company.

Board has adopted this recommendation and is arranging with the towns *en route*, Martinez, Port Costa, and Pinole, to join in the project, and a bond election to provide funds will at once be held.

The present rates are from 30 to 35 cents per 1 000 gal., and it is estimated that, if the proposed plans are carried out, the cost will be from 20 to 25 cents, reducing in a few years, through large consumption, to 15 cents.

Marin Municipal Water District.—The present per capita water consumption is 85 gal. daily, a very small quantity for the class of urban development served. This is partly due to the actual inability of obtaining water as desired, but, chiefly to the high cost, which is 50 cents per 1 000 gal. and upward. Such high rates are in considerable measure due to the topography of the country. Early in 1912 the Marin Municipal Water District was formed, covering 115 sq. miles, in which the assessed valuation is $13 000 000. In November of that year A. R. Baker, Assoc. M. Am. Soc. C. E., was appointed Engineer, and M. M. O'Shaughnessy and Edwin Duryea, Jr., Members, Am. Soc. C. E., Engineering Advisers. It is understood that steps will immediately be taken to carry out Mr. Baker's recommendations. These are:

1.—Build a dam on Lagunitas Creek about 4 miles below the present reservoir of the Marin Water and Power Company (Lake Lagunitas), on the northern slope of Mt. Tamalpais, and create a storage capacity of 6 400 000 000 gal., or 19 700 acre-ft. In this way a daily supply of 5 000 000 gal. is expected to be obtained. The water will be taken around the shoulder of the mountain in tunnels and pipes, and delivered wholesale to the various localities from a system of main supply pipes. The total estimated cost of this first installation is $2 000 000.

2.—Take over the properties of the Marin Water and Power Company and the North Coast Water Company, and in time develop all their resources, together with the proposed new work, to the full capacity, estimated at 14 000 000 gal. daily, at a total cost of about $5 000 000.

3.—An alternative plan, not recommended, of pumping water from wells alongside the Russian River, about 25 miles from the north end of the district, and conveying it through Santa Rosa, Petaluma, and other communities *en route*, each of which would probably become customers. The cost for installations of 5 000 000 and 15 000 000 gal.

daily, from this source, would be very nearly equal to those respectively recommended.

The local distribution systems, like those of the East Bay cities, are without broad design, and leave very much to be desired, particularly in the matter of fire protection and permanency of materials.

VII.—Essential Factors Affecting a Choice of Distant Water-Supply Sources.

Far-sighted planning for a large additional supply should consider and provide for the water needs, not of the East Bay region, nor of San Francisco proper, but of Greater San Francisco-Oakland as a whole. Because there is a strong sentiment in the East Bay cities against joining with San Francisco in any political or financial enterprise, at least as long as San Francisco has a predominating influence, and because of a rapidly growing realization that in many ways the two sides of the Bay are competitive, it is possible the East Bay cities will act independently.

Quantities Required for Various Dates.—The additional quantities needed by the several portions of and for all Greater San Francisco-Oakland are about as given in Table 2.

TABLE 2.

	1920	1940	1960	1980	2000
San Francisco Proper and Southern Peninsula	10	50	100	155	200
East Bay Region	12	83	215	350	480
Marin County and North Bay Region	2	5	12	23	37
Totals	24	140	327	528	717

It will probably be economically desirable to obtain from outside sources about the quantities given in Table 3.

TABLE 3.

	1920	1940	1960	1980	2000
San Francisco Proper and Southern Peninsula	0	0	0	5	50
East Bay Region	3	46	178	312	443
Marin County and North Bay Region	0	0	1	9	23
Totals	3	46	179	326	516

Doubtless it would be profitable, certainly desirable, and at least a very nice thing, to furnish water to the urban communities along or close to the conduit or aqueduct line, and to the mutual interests of all concerned that excess water be used for irrigation along that line, until needed in Greater San Francisco-Oakland. Under existing laws, this would endanger a servitude being placed on such excess water. It must be remembered, however, that even the State Constitution can very easily be changed—especially with the initiative, referendum, and recall in effect.

Discounted Present Value Only Fair Method of Comparison.—Distant sources have the serious disadvantage that, as single-conduit installations cost much less than double or triple lines of equal capacity, larger and more expensive works than present needs demand are economically required; and interest charges on initial investments mount up startlingly. Those sources which are adaptable to gradual development have a marked advantage. Greater San Francisco-Oakland may obtain water, satisfactory as to quantity and quality, from so many different sources, that, to make fair comparisons, it is necessary to outline the expenditures of all kinds, construction, operation, maintenance, depreciation and renewals, and incidental incomes, at specific dates, and reduce them to present values, using probable interest rates.

Location of Local Storage.—Another disadvantage of distant water sources is increased likelihood of damage to the conveying conduit or aqueduct. As the distance increases, other things being equal, not only is the risk of sudden interruption greater, but also the time required to make repairs, the cost of patroling, and of up-keep. To avert serious consequences in case of interruption, it is necessary to provide large, near-by storage facilities. The greater the risk the more storage is required.

Fortunately, San Francisco proper has Crystal Springs Reservoir on the Peninsula (capacity 19 300 000 000 gal., or 59 200 acre-ft.), and in a few years will have the Calaveras Reservoir (capacity 53 000 000 000 gal., or 162 000 acre-ft.), on the east side of the Bay; the East Bay cities have Lake Chabot (capacity, 4 840 000 000 gal., or 14 800 acre-ft.), with the possibility of creating the larger Upper San Leandro Reservoir (capacity, 16 700 000 000 gal., or 51 270 acre-ft.), at a cost of $3 000 000. Marin District now has Lake Lagunitas and Phœnix Lake (capacity, 382 000 000 gal., or 1 186 acre-ft.), and probably within a few years

another larger storage basin which the Marin Municipal Water District plans to build (ultimate capacity, 6 400 000 000 gal., or 19 700 acre-ft.).

The location and elevation of these local storage facilities have an important bearing on the selection of a distant source.

Earthquake Zones and Faults.—The seismic disturbances which have occurred thus far in California have been *tremblors*, and not very serious matters, provided—but only provided—their likelihood is frankly recognized, the facts concerning their occurrence thoroughly ascertained, and methods to circumvent them carefully and systematically worked out. President J. C. Branner, the eminent geologist of Stanford University, urges scientific, sane, and calm study of the "active faults" in the earth's crust in California. When these are located it will be possible to build so that when future earth slips occur, the damage will be negligible. If the wriggling line of the "1906 Fault" had been accurately known, the Spring Valley Water Company would not have had its pipe line laid over it, the water supply would not have been cut off, and the disastrous fire would not have happened.

Crossings of Waterways, Bay, and Mt. Diablo Range.—There are serious natural obstacles to be overcome in bringing water from distant sources into San Francisco. With the Sierra Nevadas to the east there is the wide San Joaquin Valley, the River, and the Mt. Diablo Range. The first of these prohibits a gravity line, except by using very long inverted siphons under high pressure, the last necessitating pumping against high head over the lowest pass, or long tunneling in very bad ground crossed by "active faults." To bring water from the northern Sierra Nevadas, requires crossing the narrower but equally low Sacramento Valley, the River, and the Carquinez Straits. All Sierra Nevada sources necessitate taking the water for San Francisco proper across San Francisco Bay. With southern sources Marin County can only be supplied through a tunnel more than a mile long under the Golden Gate. The water here is 300 ft. deep, and the crossing would probably be somewhat similar to the one under the Hudson River at Storm King on the Catskill Aqueduct.

Many local engineers fear the difficulties of tunneling the Mt. Diablo Range, regarding it as a formation exceedingly difficult and expensive to pierce. Mr. Freeman, on the other hand, regards the difficulties it presents as much less than those of the Carquinez Straits

crossing, which latter he regards as offering such tremendous obstacles alone as to dismiss immediately from serious consideration all sources which would involve it.

Conservation.—There can be no doubt that supplying municipal needs is the highest use to which water can possibly be applied. That is by no means saying that other useful requirements should not be considered at all until such highest use is fully satisfied. All needs of a region should be considered in relation to all supplies, and adjustment made to secure the maximum total economic benefits to society. This is so obvious that taking the trouble to state it seems waste of time. Nevertheless, it is usually adroitly ignored and avoided for the reason that the greatest total benefits to society may mean individual lesser benefit or greater cost to a powerful interest. The total benefits and costs are rarely divided in like proportions. To this fact is due conservation and the conservation policy—now generally accepted in theory and almost as generally sought to be avoided in individual cases.

In California, as in all the Far West, because of climatic conditions, water is more important than fertile soil and strategic position. The water resources of the Central Valley and the northwestern part of California, sooner or later, will be so conserved and apportioned as to produce the maximum possible benefits. No use can be so high as to interfere permanently with, or prevent, such a result. Unfortunately, no definite steps have yet been taken toward such an end, and this fact alone seems to justify the National conservation movement. It is extremely unsafe, however, for any interest to assume that such indifference will continue. The world moves and, in the Far West, it moves rapidly. Indeed, it is startling to look back only 10 years and see how the viewpoint of the general public has changed with regard to the exploitation of natural resources and how it has already been crystallized into fundamental changes in legislation. Any person, corporation, or municipality is most short-sighted to make investments without weighing carefully the probable changes in public opinion and consequent legislation, designed to produce a higher degree of intrinsic justice—at least for the period necessary to "unload" successfully.

Furthermore, municipalities are but mutual corporations. In Wisconsin, municipally owned public utilities have for years been regu-

lated as to service, rates, and accounting, exactly like privately owned and operated utilities; and Wisconsin's lead in such matters has been closely followed in the Progressive West.

Irrigation.—Next to municipal use comes irrigation. In discussing the growth within California, the agricultural history of the Central Valley has been touched on and the radical changes at present under way noted. The American, and particularly the western, characteristic attitude toward experience elsewhere, resulted in irrigationists having to learn by bitter experience the wisdom of the United States Reclamation Service's standard of satisfactory irrigation water supply. This standard is that all water users have ample water at all times when it can be used profitably. It involves storing flood-waters for use when streams are very low or entirely dry during the latter part of the summer. The California Central Valley has been almost the last part of the United States to find itself in this regard.

The tremendous value of the climate and fertile soil in the great Central Valley is still not appreciated. The crop adaptation is marvelous. It is conservative to say that 20 years hence an acre of properly irrigated bare land anywhere in the Central Valley will be worth at least $500, and citrus land in the foot-hills from $600 to $800. It is equally conservative to say that in the central and southern parts of the San Joaquin Valley, particularly, unirrigated agricultural land will be worth not more than from $20 to a possible maximum of $50 per acre.

Power.—Next in order of use is the development of hydro-electric power. California stands near the head of all States in the quantity of developed water-power, and yet only a fraction of its possibilities has been utilized. The cheapest fuel is oil from local fields, now costing about 75 cents per bbl., wholesale, equivalent to coal at $3 per ton, and the supply is by no means limitless. The tremendous economic importance of the power resources of the State is obvious.

The difference between the ultimate value to society of a natural resource and the commercial value of a development of that resource must be understood. Local and general economic conditions have resulted in smaller hydro-electric concerns gladly disposing of their output in blocks at high load factors to the large companies for about ½ cent per kw-hr. One of the largest power corporations in the State, with hydro-electric plants scattered for miles along the western slope

of the Sierra Nevadas, transmission lines gridironing the central part of the State, and a 60% load factor, is generating more than 40% of its energy in steam plants.

Indeed, there is a general misconception of the commercial value of "water rights." Every decrease in cost and increase in efficiency of steam plants reduces the relative advantages of water power. The steam turbine is a notable example. The "value of water rights" has lowered tremendously in the past few years, because of rate and service regulating commissions. The tendency is to regard a water right, not as an asset, but as an exclusive license for self-constituted trustees to develop a public resource and operate it for the benefit of the public, on a percentage. This change of sentiment has practically wiped out the commercial value of a proposed project controlled by a "water filing." Companies doing a tremendous business and having ample credit can wisely carry out enormous developments and secure thereby very low costs per unit of installed capacity. The rapid development and constantly lowering cost of electric generating and transmitting equipment and the progress of the art in general are other important factors.

For example, one of the recent large projects in the State, now more than half completed, is a development in which water will be dropped through six power-houses and generate 165 000 h.p., with a total cost of $130 per installed kw. or $97 per h.p. Even this will be reduced, because water from the lowest plant will irrigate a large body of land and the State Utility Commission will certainly take irrigation water rentals into account in fixing power rates. Obviously, such developments affect the value of all hydro-electric plants and projects looking to San Francisco as a market, if not throughout the whole State.

This matter has been considered at length because the Army Board evaluated the "incidental power possibilities" of the Freeman Hetch Hetchy project—115 000 h.p.—at $51 100 000. This is more than $445 per h.p. On such a basis, the water rights of the power company's complete development, just mentioned, would have to be $37 425 000. A completed hydro-electric installation feeding into a completed transmission system supplying an actually developed market, is probably worth not more than $125 per h.p.—without such market, particularly, and the means of serving it, much less. Los

Angeles is discovering this in connection with its aqueduct power, as the city itself finds it impossible to use the hydro-electric power at a high average load factor.

Navigation.—The Sacramento River is technically navigable to Red Bluff and the San Joaquin River up to Firebaugh. Both streams are much used in the lower stretches—the former to Sacramento and the latter to Stockton. Beyond these latter points navigability is at present important chiefly on account of holding down local railway rates. Consequently, navigation in this case ranks below irrigation and power uses.

Obviously, any water storage which increases the natural flow at low-water stages improves navigation. Diversion from tributaries and upper reaches of main streams for irrigation is usually, though not always, conflicting. Diversion from higher areas, entirely outside the water-shed, as a supply for Greater San Francisco-Oakland, would always be conflicting, though, with some sources, with very small low-water flow, negligibly so.

In the Sacramento Valley there are several available storage possibilities by which the flow of the Sacramento River at Red Bluff could be increased by 500 sec-ft. for 4 months, and numerous ones to provide such increase below Marysville. In this way, navigation interests could easily and relatively cheaply be protected to permit diverting enough water from any part of the Valley drainage to supply Greater San Francisco-Oakland.

In the San Joaquin Valley the situation is not so fortunate. There the water supply is so deficient, except possibly in the northern end, that the use of storage opportunities in this way cannot be afforded.

Flood Protection.—Last of all—so far as storage is concerned—comes flood protection. The 1 750 000 acres flooded in the Central Valley must always be protected by levee systems almost exclusively. Of course, storage for almost any use would help.

Senator Newlands, the author of the Reclamation Service Act, has recently introduced a bill in Congress providing $60 000 000 per year for 10 consecutive years for flood protection, of which one-twelfth is for the Sacramento and San Joaquin Rivers, and the California Reclamation Board has outlined a $50 000 000 project for the Sacramento Valley. Spending such tremendous sums for reclaiming

FIG. 15.—RELIEF MAP, SHOWING PRECIPITATION OVER CENTRAL CALIFORNIA.

FIG. 16.—RELIEF MAP, SHOWING RUN-OFF OVER CENTRAL CALIFORNIA.

bottom-lands and neglecting to prevent waste of such citrus lands through unwise distribution of water resources is foolish.

All Uses Interwoven.—All these utilizations of the Central Valley's water resources are inter-dependent. To secure the greatest total benefits to society offers no serious problems in statecraft or engineering—only an intelligent general plan. In some sections there will then be water to waste, in others a deficiency. In any event, all comers, no matter of how high or of how low degree, or of what precedence their claims, will sooner or later be made to conform with such a general plan.

California Precipitation and Run-Off.—Figs. 15 and 16 show the probable mean precipitation and run-off curves for the State, based on all the data yet collected.

It is more than unsafe to design hydraulic works in California from mean annual figures, because of dry cycles often 6 and 7 years long. The precipitation, speaking generally, is due to storm centers coming over the Pacific Ocean and passing on to the east. When the center enters the United States near Puget Sound, practically no precipitation results in the southern half of the State, but when the path lies farther south, say, at San Francisco, the entire State receives rain. For some reason these storms often pass well to the north for several successive years. Each year, in addition, there are usually three or four relatively unimportant storm centers which pass over or near San Diego. Nevertheless, it is said that the records, kept by the Franciscan Fathers at the Mission in Santa Barbara for more than 130 years, show 1 year with absolutely no measurable precipitation.

As a consequence, in the southern end of California all significant storms are general, and in dry years so gentle and distributed that the percentage of run-off is almost incredibly small. Going northward, such conditions are less noticeable, but, throughout the entire State, especially as far north as Sacramento, long dry-year cycles frequently occur.

There are few run-off data in California prior to 1901, when the State and the U. S. Geological Survey began co-operating in systematic stream gauging. There are shorter cycles of dryer years before this period, however. This fact must be kept in mind in connection with the run-off curves given. For example, one would make a grievous

mistake by using all the stream gaugings after 1902 in Fig. 17, and assuming them to be typical. There were few reservoir records prior to 1901 in the Sierras, like those at Sweetwater and Cuyamaca.

Irrigation Water Requirements.—In determining the excess, if any, of available water above the needs for irrigation in any territory, there are the two factors, irrigable area and the local duty of water. The first is simply measured, except that in some cases the greatest utilization of a large region's water resources may require modifying the natural limits, such as water-sheds.

The local duty of water, however, is as yet a matter of judgment. It varies with soil types, present and future crops, drainage, character of supply, metered or unmetered service, and extent of cultivation. Very little Middle and Northern California data are enlightening, because very few supplies are really what they should be. Water rentals on a quantity basis are the rare exception. The almost universal disposition of irrigators to use too much water is well known. Few supplies are dependable, particularly during the latter part of the irrigating season, when streams are at the lowest. This results in using excessive quantities during times of plenty, to store water in the soil, a wasteful plan, unsatisfactory in many ways. Thus water-logging and temporarily ruining large areas is the general experience in almost all western irrigation projects. Averages of current practice, therefore, are thoroughly unsafe guides; the extreme limits are too far apart.

The various State Agricultural Experiment Stations and the U. S. Department of Agriculture have made numerous experiments to check such collected data. Unfortunately, these data do not have great practical value, just as the results of acceptance trial tests on steam-power plants are not safe bases for estimating output cost per horse-power per annum.

An important economic factor is the degree of soil cultivation. When the Sweetwater Reservoir was empty and the precipitation very small, citrus trees near San Diego were kept alive with only 3½ in. of irrigation water per annum, but at a cultivation cost normally prohibitive. Dry farming could be practiced successfully over vast areas where it is economically unjustified under conditions now and for a long time obtaining. The two greatest problems in America are to stop the disproportionate growth of cities and to improve the labor situation on the farm. Assuming that 1 acre-ft. of water per

annum and a cultivation cost of $25 per acre will produce as much as 3 acre-ft. of water and a cultivation cost of $5 per acre, is the water saving justifiable? Except where the water supply must be extended

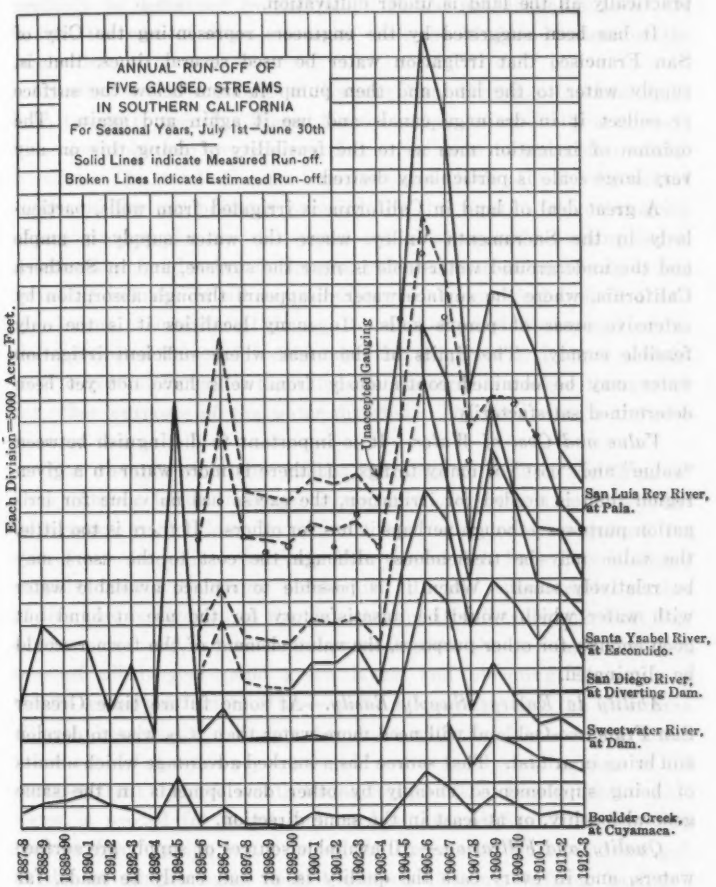

FIG. 17.

over exceptionally valuable land, obviously it is not. Experimental or theoretical and economical minimum water duties are very different things.

Many irrigation engineers believe the only safe guide is the actual water use over large successfully cultivated areas where conditions are essentially similar, where the water supply is metered, and where practically all the land is under cultivation.

It has been suggested by the engineers representing the City of San Francisco that irrigation water be used several times, that is, supply water to the land and then pump it from below the surface or collect it in drainage canals and use it again and again. The opinion of irrigation men as to the feasibility of doing this on any very large scale is particularly desired.

A great deal of land in California is irrigated from wells, particularly in the Sacramento Valley, where the water supply is ample and the underground water-table is near the surface, and in Southern California, where the surface water disappears through absorption by extensive areas of porous soils. In many localities it is the only feasible supply. The limits of the areas where sufficient irrigation water may be obtained continuously from wells have not yet been determined satisfactorily.

Value and Cost of Water.—It is important to distinguish between "value" and "cost" of many things. If there is more water in a given region than is needed for irrigation, the excess has no value for irrigation purposes—though perhaps it has for others. If there is too little, the value may be tremendous, although the cost to the users may be relatively small. When it is possible to replace available water with water which would be unsatisfactory for the use at hand but good enough for other purposes, the value element of the former would be eliminated.

Ability to Enlarge Supply Easily.—At some future time Greater San Francisco-Oakland will need more water than it is wise to develop and bring in at first. That source has a marked advantage which admits of being supplemented cheaply by other developments in the same general locality, or at least in the same direction.

Quality, and Filtration.—All available sources of supply are surface waters, and in every case the quality is, or can easily be made, far above what is generally regarded as satisfactory for large cities. Some are better in this regard, others in that; some will require immediate filtration, with others it would be unnecessary. The disposition is to insist more and more on treatment of all surface supplies, even when long

storage in reservoirs is possible. Quality standards in everything are rising, and filtration to remove coloring matter and minute organisms, even when, for hygienic reasons alone, it would be unnecessary, will probably be demanded by the public in the not distant future. Of course, the cost of filtration varies with the kind and extent of the impurities.

Sentiment.—The people of Greater San Francisco-Oakland have been taught to regard a Sierra Nevada supply as markedly better and more desirable than any other, and this fact must be given due weight.

Cost.—The cost to Greater San Francisco-Oakland is the discounted values of the expenditures required for the rights and construction of any project plus the discounted values of operation, maintenance, deterioration, and renewal charges, plus the cost of antagonistic and resentful feelings of all communities which may feel despoiled and the danger of intentional damage to much-exposed works, and minus the discounted value of incidentals such as power and water rentals.

The cost to society is the value (as the term is used in this paper) for other purposes of the water diverted. The total cost is the sum of these two.

The cost per thousand gallons delivered to him is the thing of chief interest to the average citizen, and of particular and peculiar importance to the East Bay communities. As already explained, the tide of newcomers into the State from east of Salt Lake City is almost entirely toward Southern California. If any considerable portion of this tide is diverted to the Bay regions, it will be by the East Bay communities, and, in the endeavor to do this, the striking attractiveness of all-the-year-round green lawns and blooming flowers is a vitally important factor. These media, all accentuating the California climate, have resulted in Los Angeles largely by reason of the meter water rate of 9 cents per 1 000 gal. and a flat sprinkling rate of 0.9 cent per front foot per month for all lots 150 ft. or less in depth. Less water is needed for lawns and gardens around San Francisco Bay than at Los Angeles, but, even so, the upper cost limit per 1 000 gal. at the consumer's meter cannot exceeed 15 cents without having a serious effect on the area of lawn in the East Bay district.

It is a luxurious thing to have a high mountain water supply, but it is not an obvious point in competing for the Eastern and Middle West newcomers to the State. In this day and generation, to urge a

pure water supply is about as impressive as to dilate on satisfactory police protection, or paved streets—these things are assumed as a matter of course. Green lawns and blooming flowers the year round, and especially in winter, made possible by California's distinctive climate, is constantly impressive to to-day's tourists and to-morrow's fellow-citizens, and these features must be practically universal to compare at all favorably with the southland.

It is a simple matter to take a base rate of 15 cents per 1 000 gal., meter measurement, the present or prospective consumption at any given time, the cost of operation, taxes, etc., and, with any assumed rate of interest, ascertain the capital investment which may be expended on water supplies without jeopardizing this matter of lawn development. Suffice it to say that any proposed water development on a large scale, which would make water cost more than 50% greater than the rates obtaining in Los Angeles, is practically beyond the means of the East Bay cities. This point is of little importance in San Francisco, because there are notably few and small lawns, and even with free water from now on, that city never could be made comparable in that way with Los Angeles.

VIII.—Possible Distant Sources of Supply.

The following additional sources of supply have been suggested: Eel River, Putah Creek, and Clear Lake and Cache Creek, from the northern Coast Range region; Sacramento and San Joaquin Rivers, from the delta region of the Central Valley; and McCloud River, Indian Creek, Feather, Yuba, and American Rivers, Lake Tahoe, Mokelumne, Stanislaus, and Tuolumne Rivers, from the Sierra Nevadas.

A.—Coast Range Sources.

The Coast Range sources are shown on the map, Fig. 18.

Eel River.—The water is not needed locally for irrigation. The length of conduit is much less than that for any of the Sierra Nevada sources, and, as a supply for only the East Bay cities and Marin County, is apparently well worth more careful consideration than it has received. In the construction of the project, the Carquinez Straits crossing should be made sufficiently large to serve as well for the maximum possible additional supplies, such as the McCloud, the Indian Valley, and the Feather River projects, when any or all of these may be needed.

FIG. 18.—RELIEF MAP, SHOWING POSSIBLE COAST RANGE SOURCES OF SUPPLY.

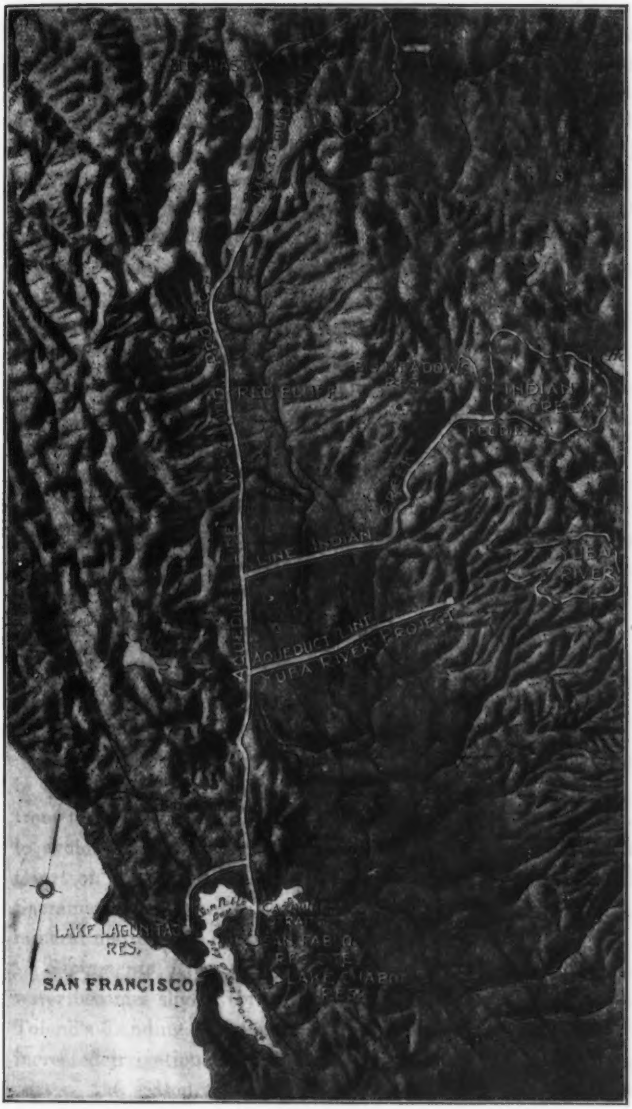

FIG. 19.—RELIEF MAP, SHOWING POSSIBLE NORTHERN SIERRA SOURCES OF SUPPLY.

Above the Gravelly Valley Reservoir site, where 180 000 acre-ft. capacity could be created by a dam 140 ft. high, is a drainage area of 326.5 sq. miles. The safe draft is estimated at 180 000 000 gal. daily, or, with a conduit of 225 000 000 gal. daily capacity, and using the large terminal storage in Greater San Francisco-Oakland, 200-000 000 gal. daily. The conduit would be so near the hydraulic grade line that reinforced concrete pipe could be used for much of the distance. The elevation of the intake is 1 000 ft., and the length of the conduit to San Francisco, *via* Golden Gate, 125 miles. No cost estimates are available.

Putah Creek.—Putah Creek is the closest mountain source. With the excellent Monticello and Guenoc Reservoir possibilities, a safe draft of about 150 000 000 gal. daily could be secured. The conduit could follow closely the hydraulic grade line to Carquinez Straits and be 60 miles long to Lake Chabot, back of Oakland. The water should all be used locally for irrigation.

Cache Creek and Clear Lake.—Within the possible limits of lake-level regulation, 600 000 acre-ft. of storage could be obtained in Clear Lake, with which a safe draft of about 195 000 000 gal. daily would be possible. This water would not be of the best, and it should all be used for irrigating tributary valley and foot-hill land.

B.—Delta Sources.

The Delta sources are shown on the map, Fig. 20.

San Joaquin River.—The low-water flow of the San Joaquin River is so small that an intake would have to be constructed where inflow from the Sacramento River could be assured, and yet be high enough to avoid salt water from the Bay. Mr. Wadsworth suggests Clifton Court on the Old River. The supply would have to be filtered. The Sacramento River water is clearer, of better quality, softer, has less mineral matter, and a much less seasonal variation.

Sacramento River.—At the mouth of the Sacramento River the water becomes slightly brackish late in the seasons of low run-off. At Toland's Landing, 5 miles above, it is always fresh. In the future, increased irrigation use will tend to reduce the flow during the early part of the season, but will probably slightly increase the low-water flow, though storage for power development and other purposes will materially increase the low flow. It is highly improbable that sea

water will ever get materially farther up stream than at present. Mr. Allen Hazen reported in 1912 that the "Sacramento River water can be filtered so as to produce a good potable water at all seasons of the year, removing the turbidity, color, and results of sewage pollution." The resulting hardness would be from 56 to 62, or about two-thirds that of Washington, Cleveland, Chicago, Pittsburgh, Cincinnati, or Louisville, and 80% more than New York or Philadelphia.

The filtration plant and an emergency intake would be near Antioch, as planned for the Richmond Water District. The total length of the line recommended by Mr. Hazen, starting about 8 miles farther up the river, at Rio Vista, running thence directly to filtration works at Antioch, and thence to Walnut Creek, East Oakland, Alameda, and across the Bay to Potrero Point, San Francisco, is about 54 miles.

Estimates on this project were with a $3 wage scale for an 8-hour day and present railway freight charges on material from the East. Taking dates for installations of 133 333 333 gal. daily, except tunnels built originally for 400 000 000 gal. daily capacity, as 1914-18, 1936, and 1975, respectively, interest at 4½%, and assuming that all plants would begin running at capacity immediately on installation, at a cost of $17 per 1 000 000 gal. for operation, maintenance, depreciation, and renewals of plant, the present value of the cost of this source is estimated by Mr. Wadsworth as $51 700 000.

Of course, no one would seriously consider installing works of 133 333 333 gal. daily capacity for a community now fully supplied and using only 70 000 000 gal. daily, nor begin to operate them to full capacity immediately on completion. Caution must be used, therefore, with this figure of $51 700 000.

The water diverted would have no value for any other purpose whatever. No power could be generated, and practically no water sold *en route*.

C.—Sierra Sources.

The Northern Sierra sources are shown on the map, Fig. 19.

McCloud River.—The McCloud River rises on the south side of Mt. Shasta, and, joining with the Pit River, forms the principal tributary of the Upper Sacramento River. It has a remarkably steady flow for California, and a minimum discharge of 1 200 sec-ft., or 770 000 000 gal. daily—amply sufficient for all possible needs. The quality is excel-

FIG. 20.—RELIEF MAP, SHOWING POSSIBLE DELTA SOURCES OF SUPPLY.

FIG. 21.—RELIEF MAP, SHOWING POSSIBLE SOUTHERN SIERRA SOURCES OF SUPPLY.

lent. Much of the water-shed is in the Mt. Shasta National Forest, and practically all the remainder, 400 000 acres, is offered for $3 000 000. All storage necessary from hygienic considerations could be had in local reservoirs. The water is not needed for irrigation, and there are storage possibilities on the river itself and elsewhere in the drainage area of the Sacramento River above Red Bluff which would more than compensate for any purpose for any quantity Greater San Francisco-Oakland could wish to divert during low-water stages. It is doubtful whether the City would ever have to do anything of the kind—certainly not for years. The comparison of this with other Sierra Nevada sources is thus practically one of cost only.

An aqueduct to Lake Chabot, in Oakland, would be 212 miles long. Mr. Wadsworth's estimate for the discounted present value of an initial installation of 260 000 000 gal. daily, 1914-20, and an additional 140 000 000 gal. daily, in 1973, is $52 500 000.

No power would be developed along the aqueduct line, but, on the project and within the controlled tributary water-shed, about 130 000 h.p. can be developed at attractive costs. The conduits, almost entirely of gravity type and of reinforced concrete, would be along the western edge of the Sacramento Valley for the entire length of the latter, and would pass close to many rapidly growing towns and irrigable land having the highest crop and fruit adaptation in the State. All excess water could doubtless be sold along the way from the very start, although not at prices fully proportionate to the cost of the aqueduct and reservoir system.

Indian Creek.—Indian Creek is a branch of the North Fork of the Feather River, with one of the best and most economical reservoir sites in America. A dam 120 ft. high would create a storage of 600 000 acre-ft. and one 220 ft. high and 900 ft. long on top, 2 300 000 acre-ft. (a capacity of 445 000 acre-ft. is equivalent to a yearly flow of 400 000 000 gal. daily). The flow line would have an elevation of 3 680 ft., and the area would be 11 500 acres. The mean annual evaporation is about 3½ ft. The run-off has been gauged from January, 1906, to date, except from January 1st, 1909, to September 10th, 1911. The average annual discharge seems to be about 480 000 acre-ft. The dam site is 4 miles, by good automobile road, from Keddie on the Western Pacific Railroad.

All the water-shed and the reservoir, covering 733 sq. miles, is in the Plumas National Forest, and, except a total of 30 000 acres, which would cost about $1 100 000, is public land. There would be no interference with irrigation or navigation, and fewer legal entanglements than with any other Sierra Nevada or Coast source, except possibly the McCloud. A total development of 140 000 continuous horse-power is possible with the final tail-race at Elevation 1 000. It has recently been investigated by the California Débris and the Conservation Commissions for flood control. It will doubtless soon be used for hydro-electric development. It has no proponents, and no surveys or estimates as a supply for Greater San Francisco-Oakland have ever been made. The conduit line to Lake Chabot would be about 196 miles long.

By State legislation, this opportunity could be held indefinitely available for future use, at no expense except the economic waste resulting from preventing power development below 1 000 ft. elevation. The McCloud Project conduit line would be followed for about half the distance, the Yuba River conduit line would be common for most of the way.

Feather River.—The water-shed of the Feather River is characterized by steadiness (for California) and quantity of run-off, and by great storage possibilities. There is no doubt that it could furnish more water than Greater San Francisco-Oakland will ever need, in addition to all possible irrigation requirements. Unless the intake were at one of the large reservoirs in the head-waters, such as Indian Valley or Big Meadows, the purifying effect of storage would be offset by mixing with run-off from areas almost but not wholly uninhabited. If the supply is to be filtered, the lower Sacramento River, except in point of hardness, is more advantageous.

Yuba River.—There is little natural storage on the Yuba water-shed, except at the highest part of the South Yuba drainage area, therefore the run-off is rapid and irregular. By a system of natural and artificial reservoirs on the South and Middle Forks, a daily supply of 165 000 000 gal. of suitable water could be obtained at reasonable cost. This could be well adapted to a combination with water from some portion of the Feather River Basin, or other sources. The water is always more or less turbid. By making a diversion near the mouth,

400 000 000 gal. daily could be secured, but at so low an elevation that pumping would be necessary and filtration advisable. Less than one-half the quantity could be spared by irrigation interests.

All these Sierra Nevada sources would be brought into Greater San Francisco-Oakland from the north, the conduits crossing Carquinez Straits. This, according to Mr. Wadsworth, would require 5 300 ft. of tunnel and 600 ft. of shafts, and would cost $1 150 000. Piercing the Mt. Diablo Range would be avoided. With the sources following there would be no crossing of Carquinez Straits, but the Mt. Diablo Range would have to be passed.

The Southern Sierra sources are shown on the map, Fig. 21.

American River.—The American River enters the Sacramento River at Sacramento. The Cosumnes, a tributary of the Mokelumne River, lies just to the south, and, owing to the topography, the upper and contiguous portions of the two water-sheds have usually been considered together in outlining power and water projects. A daily supply of about 230 000 000 gal. of excellent water can thus be obtained at reasonable cost, and diverted out of the valley without important injury to dependent irrigation interests. Approximately 62 000 net continuous horse-power could be developed incidentally.

Lake Tahoe.—Lake Tahoe is only mentioned because it seems naturally to suggest itself to many. It can supply daily about 275 000 000 gal. of excellent water, but all of it and much more is needed for the Nevada desert, where, logically and properly, it should be used.

Mokelumne River.—It is estimated that from the Mokelumne River a daily supply of from 130 000 000 to 150 000 000 gal. of satisfactory water could be secured. It is said that a storage of 250 000 acre-ft. is about the limit which can be developed on the water-shed, and that there are 200 000 acres of irrigable land dependent on the stream for water. In such case it is very doubtful whether it would not be against the best interests of society to divert out of the water-shed for any purpose more than half such quantity, or possibly any at all.

Stanislaus River.—Before getting even as far south as the Stanislaus River, the excess of water over satisfactory irrigation requirements has become very small, and here probably passes through zero and becomes minus. By taking into account the water due others by appropriations, it has been computed that about 60 000 000 gal. per day could be diverted out of the water-shed. The present water

laws of California are little less than absurd, and it is most short-sighted to stop with them. Taking into account ultimate irrigation needs, instead of rights, it is improbable that any water is properly available.

Tuolumne River.—The Tuolumne River is the source selected by Mr. Grunsky, City Engineer in 1901, and, because it contemplated transforming the famous Hetch Hetchy Valley into a reservoir, is generally known as the Hetch Hetchy supply. Mr. Grunsky proposed to bring in 60 000 000 gal. per day. In 1912 Mr. John R. Freeman increased the quantity to 400 000 000 gal. per day, or 618 sec-ft., and, among other results, was crystallizing opposition of local irrigation water users and securing by them conditions protecting many of their interests.

The Raker Bill, which Congress recently (December, 1913) passed, granted San Francisco the necessary reservoir, conduit, and other rights of way in, over, and through certain public lands, the Yosemite National Park, and the Stanislaus National Forest. Following the methods of the Conservation Policy, the grant requires:

1.—Filing customary maps, observance of National Park and Forest rules and of prior valid claims, etc.

2.—No sanitary regulations over the water-shed, other than as enumerated (those necessary in any event to protect campers in the Park from having polluted water to use).

3.—Recognition by the City of the prior right of the Modesto and Turlock Irrigation Districts (acreage not to exceed 300 000) to 2 350 sec-ft. of the natural daily flow at La Grange, whenever said districts can beneficially use it, and to 4 000 sec-ft. between April 15th and June 14th.

4.—The City to sell "such amounts of stored water as may be needed for the beneficial use of the said irrigation districts" at cost, with maximum and minimum quantities thereof which can be demanded during any calendar year. These quantities are to be fixed and occasionally revised by the Secretary of the Interior.

5.—The City not to divert out of San Joaquin Valley water for other than domestic and other municipal purposes.

6.—It defines "natural daily flow" as the quantity which "on any given day would flow in the Tuolumne River or its tributaries if said grantee had no storage or diversion works on the said Tuolumne water-shed."

7.—The immediate building of Hetch Hetchy Dam, 200 ft. high, and with a base "capable of supporting said dam when built to its greatest economical and safe height."

8.—The City to sell at cost electric power to said irrigation districts and municipalities within them.

9.—The installation by the City of 10 000 h.p. within 3 years of completing "any portion of the works adapted to the generation of electrical energy;" 20 000 h.p. within 10 years; 30 000 h.p. within 15 years; 60 000 h.p. within 20 years; and all additional possible power as soon thereafter as ordered by the Secretary of the Interior.

10.—The City to construct and forever maintain scenic roads and trails (estimated first cost $1 000 000).

11.—The City, after 5 years, to pay the Government $15 000 annually for 10 years, and thereafter $30 000 annually.

12.—The City to pay all costs of investigations or decisions required under the Act to be made by the Department of the Interior.

13.—The City to convey all its lands in the Yosemite National Park and the Stanislaus National Forest to the United States.

14.—The City to sell water at cost to the United States War Department in or near San Francisco.

The City of San Francisco formally accepted this grant with all these conditions on January 5th, 1914.

Under the Raker Bill, it is impossible to estimate closely either how much water San Francisco may divert or the cost of doing so. It is to finance the complete conservation of the water from the entire water-shed above La Grange and receive thereby the excess over local irrigation needs. The City assumes all the uncertainties. These are:

1.—Quantity of water needed for beneficial use by the 300 000 acres of land during critical years. Opinions vary from 600 000 to 1 050 000 acre-ft. per annum.

2.—Quantity of stored water needed for the beneficial use of the Irrigation Districts.

3.—Quantities the Secretary of the Interior will consider proper for the annual maximum and minimum quantities of stored water the City must furnish. This will be determined by the results of experience in the matter, and by public sentiment at that time, as reflected by the Secretary of the Interior, regarding the propriety of the City

having insisted on going for its water supply to a region where there is a deficiency instead of an excess.

4.—The available storage capacity in the water-shed. This has been usually taken at 800 000 acre-ft. The U. S. Geological Survey adopts 1 000 000 acre-ft. Mr. O'Shaughnessy, the present City Engineer, estimates it as 1 800 000 acre-ft.

5.—Quantity of run-off at the various reservoir sites and diversion points during critical years.

6.—Quantity of storage which the power projects and the irrigation districts will provide without cost to the City.

7.—Construction, depreciation, and operation cost of an undetermined quantity of storage.

The amount which, if invested at 4½% compound interest, in 1914, would construct the Freeman Hetch Hetchy project is estimated by Mr. Wadsworth as $38 901 000. This contemplates the initial installation of 160 000 000 gal. per day, 1914-20 (mean date 1917); 80 000 000 gal. per day additional, 1945-47; and 160 000 000 gal. per day additional (total 400 000 000 gal. per day), 1963-69.

These figures must be used cautiously, however, because:

1.—The City has revised the estimated cost of the first 160 000 000 gal. per day installation from Mr. Freeman's figure of $37 501 400 to about $64 000 000, and probably the figures on the other installations as well.

2.—No renewals of relatively short-lived constructions have been taken into account. There are about 100 miles of steel pipe, some of it under heads as high as 600 to 900 ft.

3.—The Freeman Hetch Hetchy project and the Raker Bill Hetch Hetchy project are very different things.

Net horse-power to the amount of 115 000 can be developed from the ultimate 400 000 000 gal. per day supply, at a cost for power-house and machinery installation of $6 000 000. A large part of this power must be disposed of at cost. For the remainder, the Railroad Commission will fix the rates, at least, practically.

So much for the cost to the City. There is also a cost to society, as any water diverted out of the shed will, within 25 years at most, be needed locally for irrigation (400 000 000 gal. per day (445 000

acre-ft. per annum) is probably enough to irrigate 200 000 acres of citrus lands or 130 000 acres of valley land). Assume the cost of putting such water on the land at $125 per acre, the value of land with water at $500, and without water at $50. The value of water, therefore, would be $325 per acre, 25 years hence. Taking 175 000 acres, the total is $56 875 000, and the present value of this (interest at 4½%) is $18 924 000.

This must also be used with caution, because:

1.—It is doubtful whether the City can obtain 400 000 000 gal. per day from this source to divert.

2.—It is not certain that all the water to be diverted is really needed for local lands. The exact limits of the irrigable area east of the 300 000 acres of the Turlock and Modesto Irrigation Districts have not been definitely determined. Neither is it known how much, if any, of this can be otherwise watered, from other streams, or by pumped wells. Where this may be practicable, the cost to society is the increase in irrigation costs capitalized.

3.—There are no reliable data to determine how many acres the diverted water would irrigate, nor the cost per acre of applying it.

4.—The time in the future, when the lands would otherwise be intensively used, may not be the 25 years taken. It is certain that relatively little of the land would be properly watered immediately, because the irrigationists have not now the financial ability. It would undoubtedly be done in less than 25 years, however.

Relative to this, it is well to remember that ultimately water will be taken from the Sacramento River near its mouth and carried south to help irrigate the insufficiently watered San Joaquin Valley. When this is done, the water will doubtless be taken along the western edge of the valley, where the rainfall and run-off is only a fraction of that on the west slopes of the Sierra Nevadas. It is certain that for at least 50 miles south of the Tuolumne, as far as Kings River, no Sacramento River water will be brought across the San Joaquin Valley to supplement the Sierra Nevada streams in their respective tributary valley areas.

In any event, the present value of the cost to society of the City's selecting this supply is tremendous. This fact, more or less clearly understood, is the cause of much very bitter feeling in the Turlock and Modesto Districts. This bitterness accentuates the un-

fortunate, but in some measure justifiable, feeling common in the City's back country that San Francisco is self-centered and selfish.

Approximate Estimates.—Although there are these several elements of uncertainty, some estimates of the quantity of water which can be secured and of the cost are necessary for comparative purposes, if for nothing else. Assume that 1 500 000 acre-ft. of storage can be provided in about 40 reservoirs very well distributed over the water-shed, and that such a storage system can be operated with 80% over-all efficiency,* including evaporation during the frequent 2 to 2½-year storage periods. From the hydrograph of the Tuolumne River at La Grange, Fig. 22, it would appear that, for the 2½ years ending November 1st, 1913, the total safe draft would have been about 1 200 000 acre-ft. per annum, with all reservoirs empty at the end of the period. During the 29 months the Tuolumne River would be dry below La Grange. Another critical period would have occurred in 1897-99. Judging from the precipitation record beginning in 1868 at La Grange—which is not a satisfactory indicator of conditions, but about the only one available—similar critical periods occurred, ending, respectively, November 1st, 1878 and 1888. In other words, such cycles seem to occur about every 10 years, covering 23% of the time.†

The average cost of 1 500 000 acre-ft. storage capacity would probably be at least $30 per acre-ft.,‡ or a total of $45 000 000. Other interests might be induced to provide half of this, or incidental power might be secured which would cause an equivalent result. Consequently, the cost to San Francisco of such a quantity of storage may be taken at between $22 000 000 and $23 000 000. As the water requirements of the irrigation districts are so much larger than those of the City, and as the ultimate use will develop so much more quickly, the mean date of construction would probably be about 1930. This would make the present value of storage cost $11 620 000.

---

* To secure such an efficiency it would be necessary to sacrifice most of the great power possibilities of the water-shed, because of different water requirements. For this reason, the City in 1912 asked the U. S. Forestry Service to permit no water storage in the Tuolumne drainage area above La Grange which the City would not control.

† See also computations by the Director of the U. S. Geological Survey. Senate Doc. No. 246, 63d Cong., 1st Sess.

‡ More probably the average cost for such a quantity of storage would be more than $40 per acre-ft. capacity.

The construction cost of the initial installation, 1914-20, exclusive of the Tuolumne water-shed storage, for 160 000 000 gal. per day, would probably be about $55 000 000, according to the City's revised estimates. Using the consumption curves adopted by Mr.

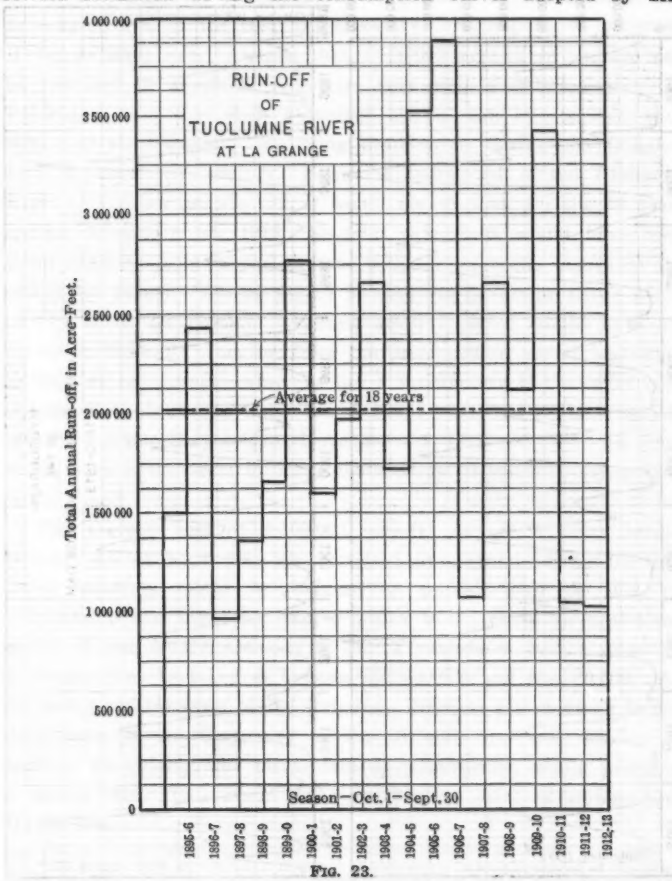

FIG. 23.

Wadsworth to secure comparative results, a second installation, increasing the capacity to 240 000 000 gal. per day, at an estimated cost of $11 000 000, exclusive of the Tuolumne storage, would be required at the mean date, 1946. A second installation, to increase

the capacity to 400 000 000 gal. per day, at a mean date of 1966, will cost, exclusive of the Tuolumne storage, about $13 000 000. The present value of these expenditures is $51 650 000. Nothing is included for renewals of short-lived materials, only initial costs. Plans which will make the Tuolumne River below La Grange dry for from 24 to 30 consecutive months, one-fifth of the time, will necessitate the acquisition of all riparian rights on the stream and many underground water rights in the region. Irrigation districts in California are classed as municipalities, and the Wright Irrigation Law, under which the irrigation districts were formed, may have to be amended before any water can be taken out of the water-shed. The cost of necessary water rights may thus be considerable.

The value to the City of the ultimate quantity of incidental power which it has been proposed to develop can, under the conditions, be no more than $3 000 000, and the mean date about 1925. The value of power to society other than the City would probably be about an equal amount. With interest at 4½% the present value of the credit to the City is $1 848 000. Other power opportunities in the water-shed have been taken into consideration in estimating the cost to the City of storage required.

The present value of the project's cost to society, the value of the water for irrigation of lands east of the Turlock and Modesto Irrigation Districts, is, say, $17 500 000. There is a credit of, say, $3 000 000 for the proposed power installation, leaving society's net cost $15 652 000.

The grand total cost (present value) is $65 454 000.

Quantity of Water Obtainable.—The City will secure per annum whatever part of 1 200 000 acre-ft. is in excess of the irrigation needs of 300 000 acres. If such needs are 750 000 acre-ft., the City can obtain 450 000 acre-ft., or 400 000 000 gal. daily. If the irrigation needs are 900 000 acre-ft., the City can obtain 300 000 acre-ft. per annum, or 273 000 000 gal. daily, and if 1 050 000 acre-ft., then 150 000 000 acre-ft. per annum, or 136 000 000 gal. daily. The quantity available is chiefly a question of the irrigation needs of the 300 000 acres of land in question.

The writer believes that the ultimate irrigation duty of water for this land will nearly equal that in Imperial Valley, California. The two regions have much the same climate, both are essentially alfalfa

and stock districts, with almost identical crop adaptations, and will doubtless have similar social conditions. The rainfall in the Turlock and Modesto Irrigation Districts averages about 9 in., and in the Imperial Valley only 3 in., but in each case practically none occurs during the irrigation season. As an offset, the San Joaquin Valley lands are much more porous than those of Imperial Valley, which are the closest ever successfully irrigated on a large scale. All irrigation water in Imperial Valley is sold on a metered basis, and is used with care and economy. Indeed, practically no drainage system has ever yet been seriously suggested, though the entire area is extraordinarily level, and the soil contained originally so much alkali that the United States Bureau of Soils condemned the region for settlement. The irrigation canals are sealed with a deposition of fine Colorado River silt, so that the seepage loss of the distribution system is quite as low as could be expected from concrete-lined canals.* Imperial Water Co. No. 1 has 101 670 acres under actual cultivation in a compact body, with the crops shown in Table 4.

TABLE 4.

Crop.	Number of acres.	Percentage.
Alfalfa	54 280	54.0
Alfalfa and barley	13 600	13.4
Barley	9 710	9.6
Corn	6 790	6.7
Cotton	6 150	6.0
Corn after barley	3 500	3.4
Melons	3 000	3.0
Miscellaneous	2 880	...
Alfalfa and corn	880	....
Vineyards	820	....

The net quantity of water actually delivered to this acreage—measurements at the highest corner of each 160-acre tract of land—during 1912 was 318 000 acre-ft., and in 1913, it was 325 000 acre-ft.

Safety.—As to relative safety, the presence of "active faults" in the Mt. Diablo Range, which will be crossed by the pressure tunnels, is a matter which many local engineers regard as very serious. Mr. Freeman holds the opposite opinion, and greatly prefers this construction to the Carquinez Straits crossing.

* "Irrigation and River Control in the Colorado River Delta," *Transactions*, Am. Soc. C. E., Vol. LXXVI, pp. 1271 and 1428-1431.

Quality of Water.—Water obtained from this source would be very soft (hardness about 20). All the contributory water-shed lies within the Yosemite National Park, and, therefore, will have no permanent population. On the other hand, with the improved transportation facilities to be made on the terms of the Raker Bill, the number of tourists, summer visitors, and campers on the water-shed will soon become a matter of importance. Taking this into consideration, together with the constantly rising standards in the quality of water supplies, Mr. Allen Hazen and Dr. Rupert Blue, Chief Surgeon, U. S. Navy Department, at the hearing before Secretary Fisher, in November, 1912, agreed in the opinion that complete filtration would be required in about 50 years, possibly sooner. Except for being softer, it would, under existing conditions, be almost exactly on a par with the water now delivered from Crystal Springs Reservoir. Judging from small reservoirs in the mountain regions, there is a possibility that greater trouble would be caused by minute organisms, such as algæ.

Possibility of Enlarging Supply.—If all the Bay communities pool their water supplies, distant supplies will probably not be required before 1945, and by 1990—taking the upper limit of 400 000 000 gal. per day as the quantity which may be obtained from this source—the combined sources will become inadequate within a period of 45 years from their introduction. Long before the latter date, it will be out of the question to secure any more supplies from that general region, and additional water will be obtainable only from the Sacramento River or some of its tributaries, that is, some of the northern sources, the construction of any one of which would be entirely independent of the Tuolumne works.

D.—Combination of Sources.

Obviously, numerous combinations of the various Southern Sierra sources can be made, as well as of those of the Northern Sierras. Some of these may offer considerable advantages.

Conclusions.

Summarizing the salient features of the needlessly complexed political, sociological, and engineering problem, it appears to the writer that the citizens of San Francisco should take stock, and determine:

A.—Whether the water problem of San Francisco is primarily one for San Francisco alone or for Greater San Francisco-Oakland.

B.—Whether San Francisco should attempt to shoulder the financing and responsibility of an entire metropolitan district supply.

C.—Whether the present water system and sources supplying San Francisco proper, when owned actually by the City and properly improved and extended, are not satisfactory and adequate for the needs of the main City for the next two or three generations.

D.—Whether the other portions of Greater San Francisco-Oakland, and particularly the cities of Oakland, Berkeley, and Alameda, are not far more concerned than San Francisco in distant water supplies.

E.—Whether, on sentiment, San Francisco can afford to invest, in a new and distant water plant, sums so vast that many other requirements more vital to the interests of the City must be sacrificed or skimped.

F.—Whether the Hetch Hetchy scheme in its final form is a sound and practical one, from the engineering standpoint, and whether engineers of practical western experience, who are best qualified to pass on its peculiarly western problems, generally endorse or generally question it.

G.—Whether the Raker Act does not strip from the Hetch Hetchy project most of its advantages and assets, leaving the City in the position of "holding the bag" for others.

H.—Whether, all things considered, the only wise line of policy for San Francisco to follow is not:

First, to consummate the acquisition of the present water system, with all its appurtenances;

Thereafter, to take the water situation out of politics by having water matters handled by a Water Board of very wide powers, and entirely independent of all other City authorities;

Thereafter, to improve, extend, and amplify that system to meet fully all the City's needs for 70 or 80 years to come;

And, thereafter, to weigh carefully the relative advantages of entering into the vast Hetch Hetchy scheme or taking up some of the more important sociological problems, with a view to the more

rapid and substantial development of the City itself, and let the other Bay cities work out their own water destiny for themselves.

Also, that the citizens of the East Bay cities should consider and decide, in addition to some of these same things, the following:

A.—Whether they should not acquire the existing water-works on the mainland, and at once improve, extend, and amplify them fully.

B.—Whether, as these cities are really in competition with Los Angeles rather than San Francisco, distant sources necessitating rates exceeding 15 cents per 1 000 gal. can be afforded.

ACKNOWLEDGMENTS.

The writer is indebted to many engineers and others for valuable suggestions and other assistance in preparing this paper. It is desired to extend grateful acknowledgment and appreciation to all of them. Especial thanks are due J. H. Dockweiler and C. E. Grunsky, Members, Am. Soc. C. E., particularly for the use of private reports and data.

DISCUSSION

Mr. Robson.

F. T. ROBSON,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has mentioned briefly the water supply—as developed and as proposed—of the East Bay shore. Several statements are startling, to say the least, and although the facts as given may be appreciated by engineers who have made a special study of the matter, yet to the Profession at large, and particularly to the local public, the acute water situation of the cities of Alameda and Contra Costa Counties comes as a severe shock. The public has long known of the unsatisfactory financial condition of these water companies, but has not been so well informed as to the water supply.

WATER SUPPLY OF THE EAST SHORE REGION OF SAN FRANCISCO BAY.

San Francisco has dominated everything in Central California for such a long time that the possibility that she will soon be passed in population and industrial growth by the cities on the East Shore has not come to be realized very generally. The cities of the East Bay region have been content to let their sister city make the fight for water alone, expecting to share in the spoils when the fight was won. It appears, however, that it will be too late to wait until San Francisco has brought in mountain water; by that time the growth of the East Shore will have been much retarded. The seriousness of such a situation deserves more emphasis and detailed analysis than that given by Mr. Cory in his paper, and it is felt that some additional facts may prove of interest.

In general, the present supply is as follows:

THE PEOPLES WATER COMPANY.

Historical.—As stated by Mr. Cory, the Peoples Water Company now supplying the greater part of the water used in the mainland cities, is the successor of nine lesser companies which have entered the field in the past forty-five years. Each supplied water to one or more of the transbay cities when they were much smaller than they are at present.

The consolidated plant does not constitute a well-designed and well-built water system. Although materials of an inferior grade were used extensively before consolidation, a big improvement has since been made. Of necessity, a number of features are obsolescent because of the rapid increase in population.

A very large part of the population lies below the 150-ft. contour, but the most desirable residence districts are on the foot-hill slopes to and beyond a 600-ft. elevation. Obviously, the water supply should be divided into at least three vertical zones with storage for each. In general, this has not been done, and could not be expected in a

* San Francisco, Cal.

plant resulting from the consolidation of a number of disjointed systems, largely unrelated, and often duplicated through competition. Mr. Robson.

The main developments were as follows:

The Contra Costa Water Company was formed in 1866 to supply the small City of Oakland, and took water from Temescal Creek, later building the Temescal Reservoir.

Somewhat later the Sausal Water Company began supplying Brooklyn, a part of the present City of Oakland, with water from Sausal Creek.

The California Water Company began operations a little later to supply the Town of San Leandro, from San Leandro Creek, and began the construction of the San Leandro Dam. Both these companies were absorbed by the Contra Costa Water Company, which, in 1875, completed the San Leandro Reservoir (Lake Chabot).

The Alameda Artesian Water Company was formed to supply Alameda, then a small detached town. A group of pumped Artesian wells near Fitchburg was the source of supply. When the population reached 14 000 this became inadequate, and as the only additional supply then possible, because of cost, was the surplus water of the reorganized Contra Costa Water Company, the latter, in 1900, took over the Alameda Company.

The Piedmont Spring Water and Power Company—1892—furnished what is now Piedmont and part of Oakland with water from tunnels driven in the hills back of Piedmont, in Diamond Canyon, and another part of Oakland from wells in Oakland.

The Oakland Water Company, about 1893, was to supply a part of Oakland and the Town of Alvarado, by a pumping plant drawing on Artesian wells near Alvarado. Within a year it acquired the Piedmont Spring Water and Power Company.

The East Shore Water Company was organized about 1898, by interests friendly to the Contra Costa Water Company, and soon after took over the Alameda Water Company. It supplied the higher parts of Berkeley and East Berkeley—then several miles north of Oakland—with water from Wildcat, Cordonices, and Wilson Creeks, from Summit and Berryman Tunnels, and from Pfeiffer Springs. When these sources proved inadequate, the only available increase within the limits of available capital was a surplus of the Contra Costa Water Company, and, therefore, the latter company soon took over the East Shore Water Company.

Prior to the advent of the Piedmont Spring Water and Power Company, in 1892, the Contra Costa Water Company, by acquiring the Sausal and California Water Companies, was in exclusive possession of the field. In November, 1894, the Oakland Water Company (which had acquired the Piedmont Spring and Water Company) first supplied Oakland with water. For the next five years competition

Mr. Robson.

was severe and wasteful—the Oakland Water Company paralleling more than 100 miles of the Contra Costa Water Company's mains in Oakland, the only territory invaded. In 1899 these competing companies consolidated, the Contra Costa Water Company continuing the business.

Thus, by the end of 1899, the Contra Costa Water Company had, willingly and unwillingly, acquired and merged seven water companies.

The Pinole Water Company was formed in 1905 to take water from the Pinole Creek water-shed and supply a part of the Contra Costa Water Company's territory, the surplus of the latter Company's supply having been exhausted by the greatly increased demand. In a few months, it was purchased and merged—before any works were completed.

In 1906 the Syndicate Water Company was formed by the financial interests behind the Realty Syndicate, which, in 1904, started acquiring and developing on an immense scale the wonderfully attractive foot-hill suburban property on the East Bay side. One part of its programme resulted in the building of the Key Route Ferry and suburban electric railway system, now carrying more than 14 000 000 passengers annually. The deficient and unsatisfactory water supply of Oakland and Berkeley threatened the success of the Syndicate's plans. Rights and holdings were acquired on San Pablo and San Leandro Creeks, and construction was begun to develop enough water to afford—with that of the Contra Costa Water Company—a supply for several years. After some negotiations, the new interests took over the old company and merged under the name of the Peoples Water Company on January 1st, 1907. At that time there were 28 000 connections, mostly unmetered, and 18 000 000 gal. per day were supplied. At present, this corporation has about 60 400 taps, 99% of which are metered; yet the consumption has been kept at about the same quantity as it was 7 years ago. Formerly, a wholesale rate was made to industrial plants and large consumers, but, when the consumption had almost reached the limit of the supply, wholesale rates were discontinued, with the result that many private wells were sunk where there was the slightest chance of securing water. The high price of water has had a bad effect on industrial growth.

Essential Engineering Features.—Fifteen sources of water supply, comprising four surface-water and eleven ground-water sources, have been used during the past 10 years by the Peoples Water Company and its predecessors, as shown on the map, Fig. 24. For the use of this map, and also the profile, Fig. 25, containing data regarding these sources of supply, the writer is indebted to the courtesy of J. H. Dockweiler, M. Am. Soc. C. E.

Lake Chabot, also called San Leandro Lake or San Leandro Reservoir, with a water-shed of 41 sq. miles, was created by an earthen

Mr. Robson.

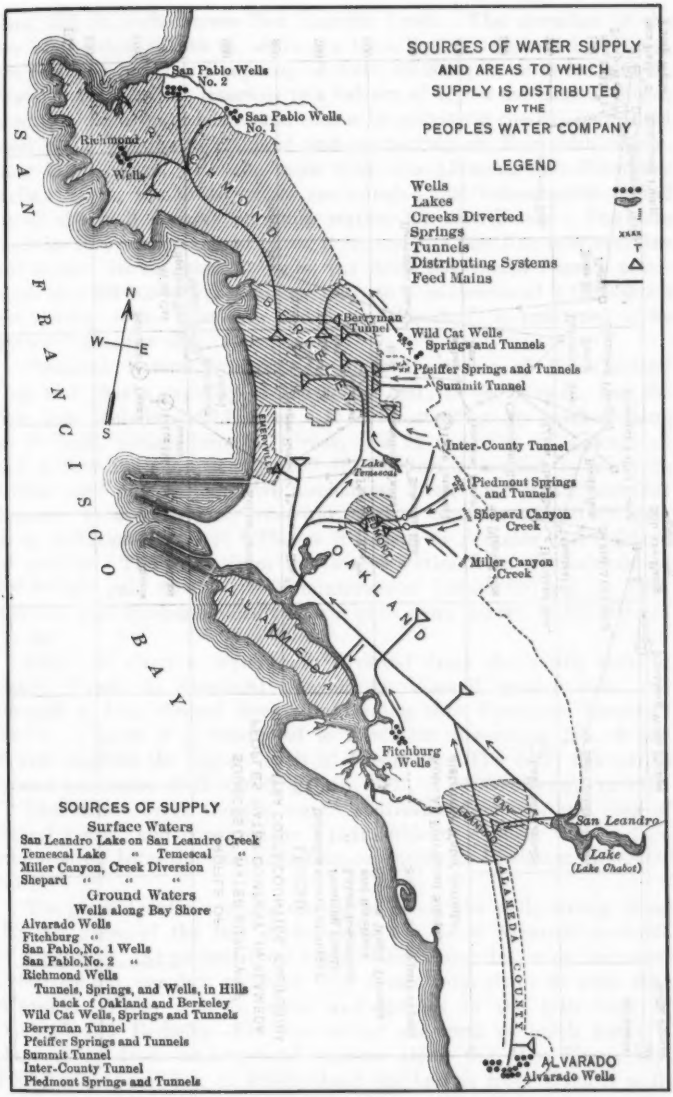

FIG. 24.

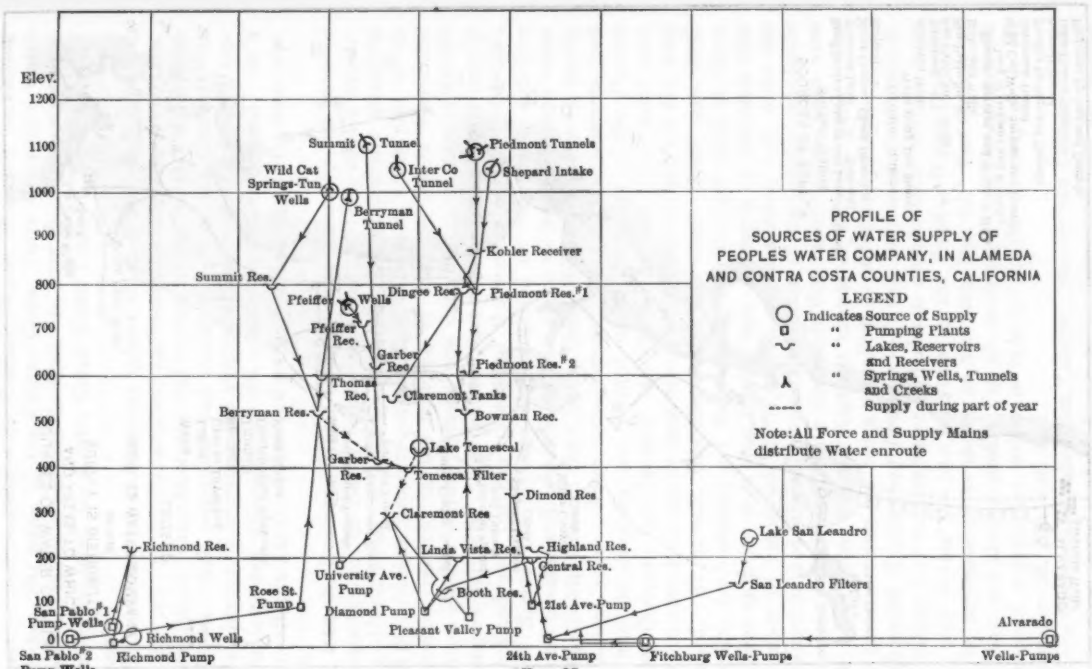

FIG. 25.

Mr. Robson.

Mr. Robson.

dam, 125 ft. high, across San Leandro Creek. The elevation of the top of the dam is 242 ft. above sea level, and, as reduced by silting, the reservoir now has a capacity of 4 840 000 000 gal., or 14 858 acre-ft. Water flows from the reservoir to a battery of Hyatt mechanical filters, then to a clean-water basin, and thence by gravity to the 38½-in. riveted steel main leading to Oakland and connecting on East 14th Street, near High Street, with the main from the Alvarado and Fitchburg wells. There, the three waters are mingled and subsequently picked up at the 24th Avenue pumping station for distribution. The dam built in 1875 was raised 10 ft. in 1892, and the flow line now contains 447 acres. In the past 10 years, the draft has varied from a maximum of 3 698 000 000 gal. during 1907, to a minimum of 2 152 000 000 gal. during 1911. The safe and dependable draft is presumed to be 6 000 000 gal. per day.

Temescal Reservoir, about 4½ miles northwest of the Oakland City Hall, has a capacity of 150 000 000 gal., or 460 acre-ft., and the flow line includes 16.75 acres. It is created by an earthen dam, 40 ft. high, across Temescal Creek, has 2¾ sq. miles of water-shed, and a flow-line elevation of 436 ft. Water is carried by a 16-in. riveted steel pipe through five mechanical filters (one Hyatt and four Loomis) to a clean-water reservoir, with a capacity of 750 000 gal., at an elevation of 375 ft. Thence it is sent to Berkeley and Oakland by gravity. The draft from this source varies from a maximum of 206 500 000 gal., in 1906, to a minimum of 126 000 000 gal. in 1904. The safe and dependable draft is said to be from 250 000 to 300 000 gal. per day.

Shephard Canyon waters are diverted from the north fork of Sausal Creek, in Shephard Canyon, by a small wooden dam, and through a 7-in. riveted steel pipe leading into Piedmont Reservoir No. 1. Thence it is conducted to Piedmont Reservoirs Nos. 2 and 3, and supplies the higher levels of Piedmont. The draft has varied from a maximum of 32 000 000 gal., in 1907, to 25 000 000 gal., in 1910.

The Miller Creek Canyon water is diverted from the east fork of Sausal Creek, and conveyed by a 2-in. pipe to connect with a 7-in. pipe leading from the Shephard Canyon source to Piedmont Reservoir No. 1.

The ground-water supplies consist of about 150 wells strung along the east shore of the Bay in five localities, from Alvarado to north of Richmond. At present these supplies are being drawn on for about 10 000 000 gal. per day, of which 80% comes from about 35 wells near Alvarado. From tunnels, wells, and springs in the hills back of Oakland and Berkeley—five sets—about one-tenth as much water is obtained as from underground sources along the Bay Shore, say, 1 000 000 gal. per day, of which about one-half is from Wildcat wells and tunnels. These ground-water supplies are not filtered.

Mr. Robson.

In addition to the four impounding reservoirs, Lake Chabot, Temescal, and Piedmont Nos. 1 and 2 (which have a combined capacity of 5 011 000 000 gal., or 15 384 acre-ft.), there are thirteen distributing reservoirs with capacities of from 158 000 000 to 28 000 gal. (total 240 000 000 gal.), and at elevations of from 80 to 950 ft.

There are five primary and six "booster" pumping stations, with capacities of 16 500 000 and 35 600 000 gal. per day, respectively, with 10 000 000 and 20 000 000 gal. as a daily average. Of the total pumpage about 48% is pumped once, 33% twice, 18% three times, and 1½% four times.

As has been said, the distribution system has about 800 miles of pipe, of which about 48% is 2-in. and less, and 50% 4-in. and less; 35% is cast iron, from 3 to 16-in.; 10% iron and steel, riveted, from 4 to 37-in.; 50% standard screw, from ¼-in. to 8-in.; and the remainder, converse, cement-lined casing and tubing.

Union Water Company of California.

The Union Water Company is the next in importance serving those communities directly across the Bay from San Francisco. It resulted from the activities of the Bay Cities Water Company formed in 1902 to supply water to all the Bay cities.

Historical.—When, in 1901, C. E. Grunsky, M. Am. Soc. C. E., then City Engineer of San Francisco, first reported on a Sierra water supply of 60 000 000 gal. per day, many engineers believed such a quantity of water could be obtained more cheaply from near-by sources. This fact and the friction between the Spring Valley Water Company and San Francisco on the peninsula and the Contra Costa Water Company and the East Bay cities on the mainland, were the underlying reasons for the formation of the Bay Cities Water Company, on October 21st, 1902. The Company acquired rights and large land holdings and outlined a project consisting of two parts—the Mt. Hamilton Project and the Coyote Project. The former is said to be capable of being developed to supply 22 000 000 gal. per day and the latter 40 000 000 gal. per day, or, combined, 62 000 000 gal. per day, approximately the quantity Mr. Grunsky planned to bring in by the initial Tuolumne, better known as the Hetch Hetchy, supply.

The Bay Cities Water Company made offers to both San Francisco and Oakland, but both were declined. Suits were instituted by the Spring Valley Water Company attacking the right to divert water from the Mt. Hamilton Project which is higher up but on the same Alameda Creek drainage area as that Company's Calaveras Reservoir and Sunol filter galleries, and by the land and riparian rights owners in the Santa Clara Valley, on the Coyote Project.

The Coyote Project, as proposed, consisted in collecting and storing surface waters in reservoirs to be constructed, one on Coyote Creek,

Mr. Robson.

another on Uvas Creek, and a third on Llagas Creek, all draining into the Santa Clara Valley. The decision of the Court in these suits will doubtless make it impossible to use this water in Alameda County.

The proposed Mt. Hamilton development would supply only 22 000 000 gal. per day, and therefore, even though the conflict with the interests of the Spring Valley Water Company did not exist, it would not be attractive, even for the East Bay communities alone. As a matter of fact, the water in question can be conserved more cheaply and delivered to any part of Greater San Francisco by the Calaveras Reservoir of the Spring Valley Company, because the latter is much nearer the mouth of Alameda Creek and the Bay cities.

In the course of these activities, the possibilities of the local underground waters were critically examined. H. L. Haehl, Assoc. M. Am. Soc. C. E., working in conjunction with C. E. Gilman, Assoc. M. Am. Soc. C. E., Manager, Edwin Duryea, Jr., M. Am. Soc. C. E., Chief Engineer of the Bay Cities and the Union Water Companies, and John W. Alvord, M. Am. Soc. C. E., Consulting Engineer, made exhaustive geological surveys, and reached practically the same conclusions, namely:

(1) That there are two distinct and disconnected bodies of underground water within the San Francisco Bay region, one reached by shallow wells less than 200 ft. deep, chiefly supplied by waters absorbed from stream overflow and the rainfall on the local alluvial fans, and to a much less, though considerable, extent by percolations through the joints and fissures of the rock rim and basin of the valley; and the other, locally known as the "Artesian" water, lying much deeper and in large measure supplied by the uptilted gravels of the Pliocene age, exposed at high elevations in the hills on the western side of the valley, where the rainfall is a maximum.

(2) That at the southern end the deep waters are truly Artesian, but the strength of the flow gradually diminishes toward the north, until in the region immediately south of Oakland the deep-seated strata no longer force their waters to the surface.

(3) That analyses of the waters of the two types taken from adjoining wells in general show no similarity, and the seasonal fluctuations of the respective water-tables are essentially different in time.*

(4) That local well-borers call these two underground water bodies "surface" waters and "Artesian" waters, respectively, and cast off

* An interesting account of the geology and geological history of the region may be found in the Report of the Committee on the Geology of the Earthquake, in the Report on the Effects of the San Francisco Earthquake, *Transactions*, Am. Soc. C. E., Vol. LIX, 1907, pp. 216 *et seq.*, and in the Santa Cruz Folio, Geological Atlas of the United States Geological Survey, Washington. Reference may also be made to the discussion on the paper "Rain and Run-off near San Francisco, California," by C. E. Grunsky, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXI, 1908, pp. 522 *et seq.*

Mr. Robson.

the former in the region between San José and the southern extremity of the Bay, because they must be pumped.

(5) That the water supplied by percolations through the fault zones, joints, and fissures, in the distorted sedimentations of the rock rim and basin of the valley, although not the most important, is a considerable and material source of supply, and cannot be neglected in any proper consideration of the sub-surface water supply.

(6) That draft on the deep-seated "Artesian" waters west of the Alameda or Niles and San Lorenzo fans or "cones", is less than on the "surface" water, and that the former are not dependent for their supply on the surface flow of Alameda and San Lorenzo Creeks.

The Bay Cities Water Company is yet inoperative, and doubtless will never do any business in Greater San Francisco. Instead, the Union Water Company, formed on December 21st, 1910, has put down many wells, scattered over the East Bay region from Richmond to Newark, and constructed several small distributing systems in various parts of the region.

Essential Engineering Features.—The collection works of the Company, shown on Fig. 26, consist of 13 small pumping plants, of which 12 are now in use. In general, each well is an individual pumping plant with a gasoline engine or electrically-driven pump. The Company states that it has a total of 122 wells, in 14 groups, with a 24-hour test capacity of 26 000 000 gal. per day, and a safe daily draft of 19 000 000 gal. Of these wells, 12 are on the San Pablo cone, 65 on the San Leandro cone, 5 on the San Lorenzo cone, 14 on the Niles cone, and the remainder outside these cones. Owing to contracts for watering lands north of Newark, the output from Plants 11 to 14, inclusive (about 11 000 000 gal. per day), are practically not available for use elsewhere. Of the remaining 8 000 000 gal. per day (which it is said may be used in supplying present urban communities) 2 666 666 gal. per day come from 23 wells, Plant 5, and 3 333 333 gal. per day from 33 wells, Plant 6.

The distribution works consist of about 91.5 miles of pipe, forming six different systems, as follows:

Three small systems in Richmond with a total of 10.4 miles in connection with Plants 1, 2, and 3; 2.9 miles connected with Plant 4; 52.6 miles as a network connected with Plants 5, 6, 8, and 9; and 25.1 miles connected with Plant 10; the last two systems are tied together. Almost all the mileage is supplying the south end of Oakland and San Leandro. The pumps deliver directly into the mains, the pressure being controlled by automatic electric devices.

Of the pipe, 39% is 2-in. and less, 72% 4-in. and less, 95.6% 8 in. and less, and the remainder is 10 and 12-in. Cast-iron pipe, from 4 to 10-in., comprises 24%, and the remainder is converse lock-joint and steel. There are 3 100 taps, of which 92% are metered, and 850 000

Mr. Robson.

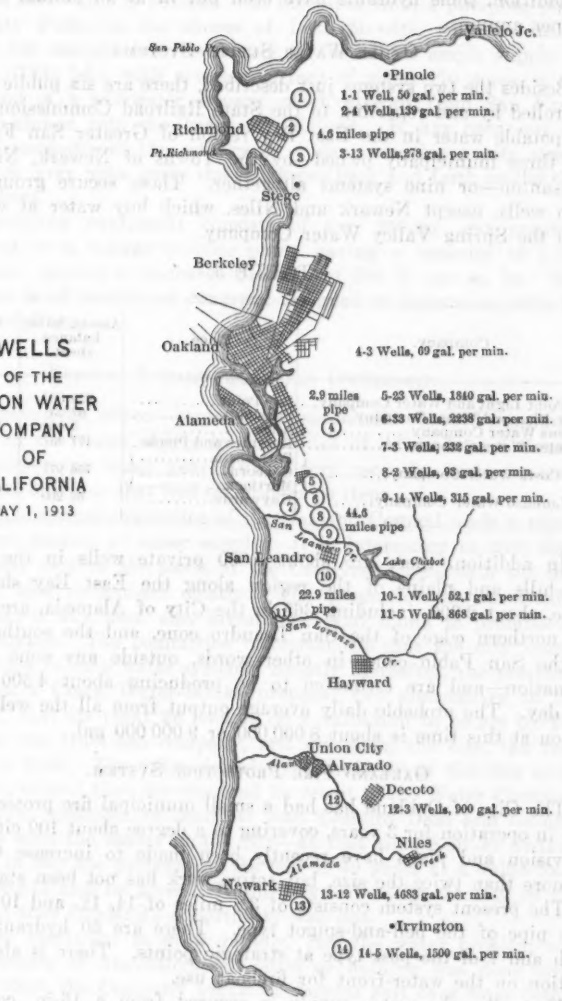

FIG. 26.

Mr. Robson.

gal. per day are being supplied at a base rate of 32 cents per 1 000 gal. In addition, some hydrants have been put in at an annual rental of $35 per annum.

Other Water Supply Systems.

Besides the two systems just described, there are six public utilities controlled by and reporting to the State Railroad Commission supplying potable water in the East Bay region of Greater San Francisco, and three municipally owned—by the Towns of Newark, Niles, and Pleasanton—or nine systems altogether. These secure ground-water from wells, except Newark and Niles, which buy water at wholesale from the Spring Valley Water Company.

TABLE 5.

Company.	Place.	Assets, latest balance sheet.	Base rate per 1 000 gal.
Bay Point Light and Water Company	Bay Point	$25 000	0.30
Black Diamond Water Company	Pittsburg	67 931	0.20
Citizens Water Company	Niles	5 000	Flat rate.
Hercules Water Company	Hercules and Pinole	177 457	0.50
Port Costa Water Company	Port Costa, Concord, Martinez	756 971	0.30
San Lorenzo Water Company	Haywards	52 200	0.40

In addition, there are about 5 000 private wells in the western foot-hills and plains of the region along the East Bay shore. Of these, about 2 300, including 362 in the City of Alameda, are between the northern edge of the San Leandro cone, and the southern edge of the San Pablo cone—in other words, outside any cone or delta formation—and are estimated to be producing about 4 500 000 gal. per day. The probable daily average output from all the wells in the region at this time is about 8 000 000 or 9 000 000 gal.

Oakland Fire Protection System.

The City of Oakland has had a small municipal fire protection system in operation for 3 years, covering to a degree about 100 city blocks. Provision and plans have recently been made to increase this area to more than twice the size, but active work has not been started.

The present system consists of 3.8 miles of 14, 12, and 10-in. cast-iron pipe of the bell-and-spigot type. There are 50 hydrants of the flush and 7 of the post type at strategic points. There is also a connection on the water-front for fireboat use.

Normally, the water supply is secured from a 16-in. connection with the mains of the Peoples Water Company, and the pipes are thus kept filled with fresh water, the necessary pressure being secured

by fire engines. In case of a large fire this fresh-water connection is closed, and salt water is pumped into the pipes from a pumping plant in the City Park, on the shores of Lake Merritt, with an intake extending far enough into its waters to insure an ample supply at all times. This lake, with a water surface of about 170 acres, is the extreme end of a salt-water estuary which extends from San Francisco Bay almost into the heart of Oakland. It has been cut off from the remainder of the estuary by a dam carrying a city street, under which large pipes carry the salt water back and forth as the tide ebbs and flows. Mr. Robson.

The pumping equipment consists of two 250-h.p. gas engines, each geared to a 4-stage turbine pump having a capacity of 1 000 gal. per min. against a discharge pressure of 200 lb. per sq. in. The pump-house is of reinforced concrete, designed to harmonize with its park surroundings.

Efforts Toward Municipal Ownership.

There have been efforts—more or less spasmodic—toward municipal ownership of the water supply by the Cities of Alameda and Contra Costa Counties for many years; until very recently, however, Oakland was the only one that had taken definite steps.

In 1874, a special committee of the Oakland Council made a report on the local sources of water supply. It is interesting to note that, even as early as this, the merit of the Calaveras Creek dam site and water-shed was recognized clearly. The properties of the Contra Costa Water-Works were also investigated and found to promise an adequate supply. The committee recommended that the city immediately secure its own water system. Shortly thereafter, the president of the Contra Costa Water-Works proposed two alternatives to the city: First, that its plant be bought on a valuation to be set by five appraisers—two from the company, and two from the city, the four to choose a fifth. The value found by a majority of the five to be binding; or, second, that the city lend its credit to the Water Company to an amount sufficient to complete San Leandro Dam and connect it by pipes with the mains in the city—at that time 8 miles distant. An option to buy the property at the end of 10 years at a value fixed as stated would also be given. Nothing was done by the city in the matter, and thus Oakland's opportunity was lost.

The city continued to grow rapidly, and the water problem was always a source of discussion, but little or nothing was done until in March, 1900, the Company began its famous suit over rates before Judge Hart who decided that the properties of the Company were then worth $7 000 000 and allowed 7% interest, 2% operating expense, and 1% maintenance. This allowance caused a raise in rates, and

Mr. Robson.

many private wells were the result. The suit cost the city $32 000 and doubtless cost the Company as much.

In 1902, Rudolph Hering, M. Am. Soc. C. E., made a report for a citizens' committee of Oakland. He advised that 15 000 000 gal. per day could be drawn from the Niles cones for the city's use.

In 1903, Desmond FitzGerald, Past-President, Am. Soc. C. E., reported to the same committee, and the next year a Board of Engineers consisting of A. M. Hunt and J. M. Howells, Members, Am. Soc. C. E., and Mr. F. C. Turner, reported to the city authorities on the adequacy of the Bay Cities Water Company's project for Oakland's water supply.

The report included a house-to-house canvass, with the following results:

Total number of private wells	718
Buildings supplied	1 436
People supplied	7 180
Water produced per day	718 000 gal.
Total capacity of tanks	3 467 000 gal.
Maximum and minimum depth of wells	681 to 18 ft.
General average depth	100 ft.
Population supplied	10 per cent.

Doubtless influenced by these reports, by the activities of the Bay Cities Water Company, which was threatening to invade its territory, and by the controversy with the city over rates, the Contra Costa Water Company offered either to sell or lease to the city, at a value determined by two men who should select a third if necessary. The city took no steps, and the offer was finally withdrawn when rates were fixed on a valuation of $4 700 000, the city ignoring the decision of Judge Hart giving a value of $7 000 000. This case was then on appeal to the Supreme Court.

In June, 1904, Judge Gilbert granted an injunction against the rates fixed by the city, but required the Company to file a bond for $130 000.

In October, 1904, five water supply propositions were submitted to the city, chiefly by the Bay Cities Water Company which was making every endeavor to break into the territory; and in March, 1905, an election was held on an offer submitted by the Bay Cities Company. The campaign will long be remembered as the hottest and most spectacular known in Oakland. A large sum of money is said to have been spent by the opposing water companies. The vote resulted in 4 369 for and 5 207 against the proposition.

Since that time, the water problem has been before the people continuously. The suit started in 1904 has not yet been decided. The Contra Costa Water Company has merged with other companies,

until now the corporation is known as the "Peoples Water Company". The Bay Cities Water Company has surrendered its activities to the Union Water Company. Mr. Robson.

The population has grown steadily, and the several communities on the East Shore now have the same water problem confronting them that Oakland left unsolved in 1874.

Financial and physical conditions make it almost impossible for one community to secure an adequate water supply without joining with others. This has been long realized, but the laws of California made no adequate provision for help. In 1909, a law following more or less closely the one under which the Metropolitan Water and Sewerage Districts of Boston and New York are operating, was passed by the State Legislature, but nothing has been done to organize a district because of alleged defects. At the request of the smaller communities, therefore, it was modified in 1911 to give them more representation. The present law permits any number of municipalities within the same county, as well as unincorporated territory, to unite and form a Municipal Water District.

In 1912, petitions were prepared and circulated to form a district, under the law of 1911, consisting of the municipalities of San Leandro, Alameda, Oakland, Emeryville, Piedmont, Albany, and some unincorporated territory, all in Alameda County. Sufficient signatures were finally secured, and it was thought a district would be formed. However, the Supervisors of Alameda County, who had the power to call the election, kept postponing the matter for one reason and another, until the present year, when an election was called for June. The Peoples Water Company put the stock control of the company, together with an option to sell its entire properties, the price to be fixed by the State Railroad Commission, in the hands of an Oakland bank.

Strong opposition to forming the district immediately appeared, a campaign of vituperation by the opponents followed, and attacks were made on the law, the water company, and the supporters of the measure. It seemed impossible to convince the electorate of the gravity of the situation, and even the majority of the newspapers were only lukewarm or actively opposed.

Due to the strenuous efforts of Mayor Heywood, of Berkeley, a majority of some 300 or 400 was given in favor of the district there, but this only nullified the adverse vote in the smaller communities, as Oakland returned a majority against the district of about 2 500. Less than 50% of the registered vote was cast. This defeat was a body blow to those who knew the conditions. Nothing has been done since, and it is not known what steps can or will be taken. A new law has been prepared, but should it be passed there will doubtless be as much opposition as before.

Mr. Robson.

In the meantime, the Peoples Water Company was becoming more involved, financially, and in July, 1914, interest on its bonded indebtedness was defaulted. The affairs of the Company have been put in the hands of a committee of bankers, and protective committees of bondholders have been formed. No satisfactory reorganization plans have been given out, and the general financial conditions resulting from the war in Europe leave little of an encouraging nature apparent in the immediate future.

Conclusion.

No satisfactory solution of the water supply problem for the East Shore cities can be reached until these can be joined in one district or organization for that purpose. When this has been accomplished, such properties of the Peoples Water Company as are necessary must be purchased and the development of local sources completed. The district would then be in a position to purchase and distribute water from any source available.

Half of the total present and proposed supply of the Spring Valley Water Company comes from Alameda County sources. Under existing laws, if San Francisco purchases the Spring Valley Company, the taxes now levied by Alameda County on this property would not have to be paid by San Francisco. This would mean a large decrease in revenue for general county purposes.

After forming a district and purchasing the properties of the Peoples Water Company, the East Shore cities should buy the Alameda County system of the Spring Valley Company, thus relieving San Francisco of this portion of the purchase cost and making available a larger sum for acquiring distant mountain supplies.

It is a striking commentary on the foresight of the Spring Valley Company, when it is known that for years it has had a deeded right of way from its Calaveras Dam to the City of Oakland.

Mr. Le Conte.

L. J. Le Conte,* M. Am. Soc. C. E. (by letter).—The writer is greatly interested in this timely paper. The author has certainly taken a very wide grasp of the whole complex situation, and in arriving at his conclusions has given due weight to all the important factors which influence a wise decision.

In comparing several schemes in which the construction cost is nearly the same, all the minor items—cost of operation, maintenance, depreciation, renewals, and incidental incomes—of course, are factors; but, when the first cost of construction is vastly greater in one case than in another, consideration of these smaller items can be omitted as they have no bearing whatever on the conclusion drawn.

Undoubtedly, the wisest policy for San Francisco is to develop, to the fullest extent possible, local supplies which will probably amount

* Berkeley, Cal.

Mr. LeConte.

to 200 000 000 gal. per day, and be sufficient for 80 years to come. The city should then develop the pumping works at Moore's Landing on Old River, San Joaquin, and force the water up to Altamont Reservoir —capacity 1 000 000 000 gal. Thence supply mains should lead to the extensive natural gravel filter beds in Li ermore Valley, and thence to the several large storage reservoirs in the Alameda Creek water-shed.

The first development will be for 50 000 000 gal. per day, which will be sufficient for 25 years more, or, say, until 2000 A. D. The cost of these new developments up to this time will be:

Peninsula	$40 000 000
Pumping works	10 000 000
Total	$50 000 000

thus making a unit cost for development of $200 000 per million gallons per day. Moreover, distant future expansions of the supply can be readily made at the same unit cost for development.

The East Bay region, by full development of all local sources, can obtain from 30 000 000 to 40 000 000 gal. per day, which will be sufficient for from 10 to 15 years to come. At the close of this period—1930—the best available outside source will be, likewise, at Old River, just above the junction of Indian Slough, some 12 miles above Marsh's Landing, which will be the site of the pumping works.

Thence, two supply mains will lead along the straits and bay shore to Berkeley, Oakland, and Alameda. The first development should be for 100 000 000 gal. per day, which would call for the expenditure of $20 000 000. This additional supply would be sufficient for 60 years to come, or until 1975, and would show a unit cost of development of $225 800 per million gallons per day, delivered; and, moreover, the expansion of the supply, in the more distant future, can be readily made at the unit cost of $200 000 per million gallons per day.

These figures show conclusively that the distant Sierra supplies are undesirable, from every point of view, as will now be demonstrated.

In 1901, Mr. Grunsky reported that the Hetch Hetchy scheme, developed to 60 000 000 gal. per day, would cost $32 000 000, or $533 000 per million gallons per day, or nearly three times the cost of development of the local supplies near San Francisco. Likewise, in 1912, Mr. Freeman reported, with reference to the Hetch Hetchy scheme, that the first development for 160 000 000 gal. per day would cost (revised estimate) $64 000 000, showing a unit cost of development of fully $400 000 per million gallons per day. It would finally appear that this distant source of supply is vastly more expensive and is, therefore, undesirable.

Delta Sources.—The combined low-water flow of all the rivers naturally emptying into Carquinez Straits is now approximately 7 200

Mr. Le Conte.

cu. ft. per sec., during the dryest seasons on record. This is simply the surface or visible flow, and does not include the underground supply, which would probably increase it materially, if it were known; but, even the minimum (taken at 7 200), will give a reliable supply of 4 615 000 000 gal. per day. Now, it is a well-established fact that the large future hydraulic developments in the great Central Valley of California—in the way of irrigation, power, flood control, and extensive reclamation and irrigation works at and near Tulare Lake—will collectively tend to increase materially the low-water flow of all the rivers in the delta region.

The great works at Tulare Lake and vicinity will certainly add practically 10 000 sq. miles to the direct water-shed of the San Joaquin proper, and will certainly add 2 000 cu. ft. per sec. to the low-water flow of the river at a point just above Firebaughs. This result, combined with the underground return flow from the great irrigation fields on both sides of the river, will ultimately swell the low-water flow of the San Joaquin River to fully 6 000 cu. ft. per sec., thus greatly improving the low-water steamboat navigation on the entire river, to the everlasting benefit of the public in general.

The same beneficent results will also take place on the Sacramento River, and the writer is of the opinion, therefore, that fully 10 000 000 000 gal. per day can be considered as the reliable delta supply in the distant future.

Of course, subsidence and filtration, sooner or later, are to be expected for all supplies taken from the delta; but, naturally, this work is reduced to a minimum by placing the intakes on the south or Old River side, where long experience shows turbidity to be a minimum.

The quantity proposed to be taken from the delta supply, in the near future, is only 150 000 000 gal. per day, or 3% of the total, hence it can safely be said that there will be no trouble whatever from salt water.

In conclusion, it would appear that San Francisco and the East Bay region can both safely lay aside the idea of calling on the distant Sierra supplies for the next 100 years; and they will certainly be far better off financially by doing so.

Mr. Grunsky.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—In Mr. Cory's presentation of this subject, which is of vital importance to a flourishing and fast growing western section, there is a marked departure from the ordinary treatment by an engineer of an engineering problem. He has endeavored to present a picture of the local circumstances of growth and development of San Francisco Bay communities and of the factors which influence this growth, in order that due weight may

* San Francisco, Cal.

Mr. Grunsky.

be given to social, industrial, agricultural, topographic, and hydrographic conditions when the question of a water supply for the Greater San Francisco of the future is considered. The result is a paper full of interest to the California engineer, but with only few points that may call forth some comment from the engineer who deals with water supplies from the eastern standpoint.

It is plain that the author favors the development of local sources of water supply to the limit, before going far afield for a mountain supply of a higher grade.

The established company, the Spring Valley Water Company, formerly known as the Spring Valley Water-Works, has a developed supply of 35 000 000 gal. per day. This company is at present supplying in excess of this quantity, but at the cost of a gradual depletion of its storage. In California the rain which produces run-off falls within the consecutive 6 months, November to April. There may be from 2 to 3 years in succession with only 50%, or but little more than 50%, of normal rain.

In the water-sheds from which San Francisco's present supply is obtained, the normal rainfall ranges from about 15 to 50 in. per annum (the latter covering a few square miles only), and, in the years in which the rainfall is but little in excess of the minimum, which may be as low as 40% of the normal, there is hardly any run-off. Due to these conditions, there is need for storage, either on the surface or underground, of practically a 3 years' supply, if the local sources alone are to be made dependable.

Due to this fact, the supply from near-by sources involves, first, large reservoir capacity, and second, in the absence of filtration, the control of vast areas of water-shed, in order that by such ownership adequate sanitary protection can be afforded. The Water Company, in line with these requirements, has constructed reservoirs on the peninsula south of San Francisco, which have an aggregate capacity of about 28 000 000 000 gal., and is now constructing an additional reservoir on the opposite side of the bay, on Calaveras Creek, a tributary of Alameda Creek, which will more than double this capacity. The Water Company, furthermore, in order to protect the quality of the water, and also to safeguard rights to the underground waters of the Livermore Valley, has acquired and holds the fee to more than 100 000 acres of land, much of which, by reason of use as water-shed or as reservoir area, is made non-available for agricultural and residence purposes. The collecting ground is but slightly removed from the bay margin, and is generally of the low rolling hill type. Nearly if not quite one-half of the present San Francisco water supply comes from wells in the Livermore Valley and from the gravels in Sunol Valley. The Sunol gravels are recipients of the summer flow of Calaveras Creek and of lesser feeders of Alameda Creek, and in

Mr. Grunsky.

a small measure afford sub-surface storage. The water is collected from the gravels in a filter gallery.

The wells in the Livermore Valley near Pleasanton were originally Artesian, but the water-table has been drawn down by pumping, so that all water obtained from this source is now pumped.

The combined supply from the Pleasanton wells and from the Sunol gravels, after being carried across the Bay of San Francisco from the Alameda to the peninsula side, is pumped into the Crystal Springs main, so as to arrive in the city at an elevation of about 165 ft. Certain quantities of this water, according to requirement, are pumped to higher levels.

The water intercepted at Pleasanton and at Sunol is that which under natural conditions would have aided in keeping the Niles gravel cone, the delta cone of Alameda Creek, supplied with water. By this interception the natural period of flow of the creek has been reduced, and in some measure the sub-surface waters of a fan-shaped area expanding with distance westward from Niles toward San Francisco Bay have been reduced. This sub-surface supply is drawn upon, as Mr. Cory explains in his paper, by the pumps at Alvarado and elsewhere which supplement the Lake Chabot and other local supplies of Oakland, Alameda, and Berkeley.

It seems probable that the gravels of the Alameda Creek delta cone are being already drawn upon for more water than they can continuously supply. The water-plane near the pumps is lowered below sea level. It remains to be seen how long the draft of the past upon such wells can be maintained without impairing the quality of the water beyond the allowable limit.

The possibility exists, as Mr. Cory points out, of making additions to the developed local supplies, particularly for the cities on the east shore of the bay; but this water development, as in the case of the San Francisco supply, implies the acquisition of large areas of water-shed and of near-by reservoir sites, and, in view of the low, undesirable nature of the collecting ground, ultimate filtration. All this will be at a cost not materially, if at all, less than that of first-class mountain water.

The fact is generally recognized that the population centering around San Francisco Bay cannot depend long on the water from the so-called near-by sources, but must soon go to some remote source for an adequate supply.

The question naturally arises: Which of the remote sources will be the most available? Pumping from the San Joaquin or from the Sacramento River has frequently been advocated, and much is made of the fact that inferior water to that which these streams could provide is made fit for consumption elsewhere by filtration and by treatment with hypochlorite.

Mr. Grunsky.

Although this may be true, no one who has the choice would advocate the preparation of a filthy water for domestic use when, within the limit of the means at command, a pure mountain water can be made available.

On the basis of an exhaustive analysis, the writer reached the conclusion in 1901 that the cost of developing and delivering a Sierra Nevada supply of water would not be greatly in excess of developing and delivering an equivalent quantity from local sources. The result of his investigations is embodied in a so-called progress report published in the Municipal Records of San Francisco, and his conclusions have been confirmed, particularly in so far as the selection of Tuolumne River as the best source of supply is concerned, by subsequent investigators for the City of San Francisco.

If the city acquires the properties of the Spring Valley Water Company, at the price at which they are to be shortly submitted, it will be at a cost per million gallons of developed water with which the cost of water from the Sierra Nevada, if brought to the bay region in a quantity not less than 60 000 000 gal. per day, would compare favorably.

It would be out of place to attempt a review of the studies which led the writer to make the recommendation that the city make application to the Secretary of the Interior for the right to store waste flood-waters in reservoirs to be constructed at Lake Eleanor and at the Hetch Hetchy Valley, the latter on the main branch of the Tuolumne River; but, though making this definite recommendation and thereupon making the application for the city, through the Mayor, the writer has always been a strong advocate of the acquisition by the city of the established water-works, to which the mountain source of supply would be added.

The writer, as City Engineer of San Francisco from 1900 to 1904, was required to report on a water-works entirely independent of the established system, but, in doing so, he called attention to the proper course to be taken by the city. It is needless to say that he has been disappointed in the result of subsequent proceedings.

The city's application for reservoir sites met with opposition which was directed by Spring Valley Water Company officials. These officials succeeded in alarming the two irrigation districts which were dependent on the Tuolumne River as their source of supply, and thereafter the Water Company, the two irrigation districts, and misguided Nature lovers, actively opposed the granting of permits to San Francisco to use the two selected storage sites.

Secretary of the Interior Hitchcock advised that Congressional action in the matter should be sought. His successor, Secretary Garfield, recognized San Francisco's rights, but made the permit which he issued subject to certain conditions, the most onerous of which

Mr. Grunsky.

was the one requiring that the lesser reservoir, Lake Eleanor, be developed first. As the permit was revocable, the next Secretary of the Interior, Mr. Ballinger, unfriendly to the San Francisco project, issued an order to San Francisco to show cause why the permit, in so far as it related to the Hetch Hetchy Valley, should not be revoked.

San Francisco was thus put on the defensive and, due to lack of confidence of various of her official departments in each other, placed this case in the hands of an expert called in from the East. The natural result was that thousands of dollars were needlessly expended in the accumulation of a mass of statistical information, and plans were outlined, not for the San Francisco water supply alone, but for a project to divert from the Tuolumne River more than 600 cu. ft. per sec., and to make use of this water until such time as the cities near the bay require it, for irrigation in the bay region.

It was pointed out in the resulting reports that the earlier project, for an initial unit of 60 000 000 gal. per day, was far below the yield of Tuolumne River, and that the city should undertake the larger project in order to perfect its claim to a larger quantity of water. No assent, of San Francisco or of any of the other cities supposed to be interested in the larger project, has yet been obtained, or has ever been asked for.

This ambitious project when presented to the Secretary of the Interior led to violent opposition on the part of the owners of land naturally irrigable from the Tuolumne River. These land owners were determined that, if any surplus water in excess of the needs of San Francisco were to be used for irrigation, it should not be used on the other side of the Coast Range.

The representatives of the irrigation interests were therefore in Washington at the hearings, and they neatly accomplished the discomfiture of San Francisco. By claiming that the river would not always afford water enough both for irrigation and the municipal requirements of the Bay Cities, 400 000 000 gal. per day according to the tentative project, the city's experts were put to it to show that the water supply was ample. They did this, at least to their own satisfaction, and then the demand was made by the irrigation districts that, this being so, the permit if granted should be conditioned on the irrigation districts first receiving all the water which they could use beneficially before San Francisco takes any, and that, to the extent necessary to protect the districts in such use, they should be allowed to take San Francisco's stored water at cost.

Instead of refusing to surrender first right to all stored water, the city fell into the trap, as can be seen by reference to the "Raker Law" cited by the author, under which certain rights were granted to San Francisco.

Mr. Grunsky.

The city's representatives at Washington should have insisted on her prior rights. There should have been no concession of rights in the stored water to the irrigationists. The courage to do this was lacking. At the same time there might well have been, as the writer has always advocated, a cordial co-operation with the irrigation districts, because the city, by storing much more water than called for by its immediate needs, would have been in position for many years in the future, probably for 25, or more, to give annually large volumes of stored water free of cost to the districts, thereby saving to them the need of increasing their fall supply by storage of their own.

San Francisco has apparently now waived her prior rights to the stored flood-water of Tuolumne River. When there is a shortage of supply, it will fall on San Francisco, not on the irrigation districts, which, except for the concession made, as explained, would have had no rights whatever in the water stored by San Francisco, provided, of course, that this storage was made subject to the acknowledged prior rights of the districts to the natural flow of the stream to the limit of these prior rights.

San Francisco, under the Raker Law, is to expend from $500 000 to $1 000 000 on the proposed storage works in excess of her own requirements in order to be in a better position to meet the obligation, which she has apparently assumed, to supply some stored water to the irrigation districts.

San Francisco, under the same law, will be required to pay for the appropriated water, which should be hers without cost, under State law, at the rate of $15 000 per year for 10 years beginning in 1919, thereafter $20 000 per year for 10 years, and thereafter $30 000 per year. The present value of these payments exceeds $300 000.

San Francisco must pay excessively for the Government land occupied by its dam sites, by its reservoirs, and by its tunnels, conduits, power-houses, transmission lines, and the like. For these lands, of little or no value (the city already owns the fee of the major portion of the level land in Hetch Hetchy Valley), there must be given in exchange lands of greater value acquired by the city but not necessary in connection with the project.

San Francisco, at the direction of the Secretary of the Interior, must construct roads and trails in the National Forest Reservation in which Lake Eleanor and the Hetch Hetchy Valley are situated, at a cost of from $500 000 to $1 000 000, and must provide for the maintenance thereof.

San Francisco is compelled, too, to develop power and to sell a large part of this power at cost in Modesto and Turlock irrigation districts. Perhaps the cost will be determined so as to include a part of the storage, perhaps not, because storage was essential for the other purposes. The sale of power at cost will be of little if any

Mr. Grunsky.

benefit to the San Francisco water-rate payer. The remaining power will be available for use in San Francisco. Its transmission will be over lines about 150 miles in length. It would probably cost less to develop the same power in San Francisco with oil at 75 cents per bbl. than to develop the water power and deliver it over electric wires. Consequently, although of economic value to society, the power feature is likely to prove a burden, and not an advantage, to the project as a whole.

San Francisco has voted bonds for the construction of a 60 000 000-gal. per day project. The bonds voted amount to $45 000 000. These bonds are not available for the new 400 000 000-gal. per day project based on conditional rights to water and on the requirement that a large part thereof be spent in a commercial venture involving the sale of power. The city is proceeding, however, in the development of the power as though its rights in the matter, particularly in reference to the use of this bond money, could not be questioned.

The Hetch Hetchy bonds were voted in November, 1909. They cover a project, as stated, for a supply of 60 000 000 gal. per day to be obtained from Lake Eleanor under the Garfield permit. They cover also an expenditure possibly of $7 000 000 or $8 000 000 for a distributing system of reservoirs and pipes in San Francisco. They were voted with the understanding, so expressed in the ballot, that, if the purchase of the Spring Valley Water Company's properties in their entirety were sanctioned at the same time by the voters, only $30 000 000 would be available for the works necessary to make the Tuolumne project the auxiliary supply to the established system. The purchase of the Spring Valley system for $35 000 000 at the same election was lost by a few votes short of the necessary two-thirds.

At the time the city thus voted bonds, there should have been created a Board of Water Supply, free from politics. This was not done. The administration at that time and the administrations that have followed, would not let go. The Mayor, who names the Board of Public Works, and who practically selects the City Engineer for the Board of Public Works, the Supervisors, with the Public Service and Finance Committees, the City Attorney, the Board of Public Works, and the City Engineer, all have a hand in the game.

There is no programme as yet for any change. Within a year there was named a Board of Consulting Engineers to pass upon the hydro-electric features of the first power installation under the unauthorized project, understood to be for 50 000 h.p. These engineers were designated by name in the City Engineer's request for their appointment. From this circumstance alone, it is to be inferred that the political management of the city's water project will be continued. Deplorable as this may seem, it is yet possible that competent management will not be too greatly hampered by political

obstruction and political direction; and the hope may be expressed that, despite the unfortunate circumstances of the past, San Francisco may yet achieve an adequate and in every way satisfactory water supply. Nevertheless, the danger should be recognized that competent management of to-day under the political system may be followed by incompetent or even corrupt management to-morrow. Mr. Grunsky.

It will be seen from the foregoing that the Hetch Hetchy project under the Raker Law is not the writer's Hetch Hetchy project, and that the new project for water for the entire bay region has not yet been given proper standing by the voters of San Francisco, nor has it yet received the necessary study to determine its main structural features.

Meanwhile the city has made endeavor to buy the established waterworks. According to the latest proposition, to be voted on some time next spring, the Water Company will be allowed to retain several thousand acres of valuable land in and adjoining San Francisco, besides some 5 000 acres of land in Livermore Valley. The value of the Pleasanton wells as a part of the system will be reduced because the maximum draft on them is to be limited to 15 000 000 gal. per day, and because the ownership of the 5 000 acres will carry with it the right to draw on the Livermore gravels for all the water that may be needed on these lands. As these lands are fertile and lie in a region with a mean annual rainfall of only 15 in., the demand for water by them will in time be such that there may not be much water left in the gravels for San Francisco. It seems unfortunate that in the agreement for purchase the limit to 15 000 000 gal. in a single day has been made, because in the future, when San Francisco has a gravity mountain supply, the pumped water from Pleasanton wells will have chief value as an emergency supply, and when used in an emergency there should be no restriction on the quantity to be taken in a single day.

The author discusses the local water supplies as though their development, in advance of a good mountain supply of unquestionably superior quality, was a matter of course. If this is his view, there are others who are not convinced that, even on the score of cheapness alone, the development of the local sources first can be justified, and, when quality, quantity, cost, and reliability of service are all taken into account, it is hard to see how any other conclusion can be reached than that the mountain source is the next one which should be developed. There should be 60 000 000 gal. per day added to the supply at present available, and this should be mountain water.

In summarizing the estimate of the total ultimate safe draft for municipal purposes on near-by sources of supply, the author combines the developed and the undeveloped supplies, referring to the aggregate as obtainable at a reasonable cost.

Mr. Grunsky.

He includes as additional sources all or in part, though perhaps not at the estimates noted in Table 6, which are those of Messrs. Chittenden and Powell.

TABLE 6.

The Peninsula Coast streams, at	50 000 000	gal. per day.
" Ravenswood and Alviso Wells, at	20 000 000	" " "
" Calaveras and San Antonio Branches of Alameda Creek, at	90 000 000	" " "
" Area tributary to Livermore Valley, at	40 000 000	" " "
Total	200 000 000	" " "

Of this quantity (which no doubt includes some over-estimate), only about 15 000 000 gal. per day are actually developed. In the development of the remainder, as already stated, the cost—per million gallons of daily supply—may be as much as, or more than, that of the water from the Tuolumne River, if brought down in a first unit of at least 60 000 000 gal. per day. Some of this remainder will not be obtainable except at the expense of other communities or at a cost to society, which is as necessary to consider as that charged by the author to a Sierra supply.

He includes also from 12 000 000 to 13 000 000 gal. as being furnished by pumping from the Niles gravel cone, and is right in questioning the permanency of a draft of this quantity, and he includes a large development from small creeks in the hills to the east of Oakland, aggregating 21 000 000 gal. per day, and at present developed to but a small extent by the San Leandro Reservoir. When the cost of filtering is considered, and the cost to society, by reason of the occupation of valuable territory, these sources will probably be found to be as expensive as an adequate Sierra supply.

Whether or not this is actually the case, the fact remains that a 60 000 000-gal. first unit from the Tuolumne is within reach, from the standpoint of cost. The development of additional local sources is to be discouraged and not encouraged. The high-grade mountain water should be made available before the possible but improbable development of the nearer sources is awaited.

The writer's conviction remains unshaken that the private concerns on both sides of the Bay of San Francisco should be bought out by the people, and that the entire bay community should then join in perfecting and carrying out as speedily as possible the Tuolumne project, but with suitable modification of the Congressional permit, which is unfortunate not alone for San Francisco, but also for all Western States, in this, that it establishes a dangerous precedent.

The water supply problems to the northward of San Francisco Bay are separate and distinct from those of San Francisco and the East

Bay cities, and need not be brought under discussion in connection with the larger San Francisco problem. Mr. Grunsky.

The author presents a diagram, Fig. 15, supposed to represent the latest information relating to rain distribution in central portions of California. This should be used with caution. The precipitation does not increase from north to south in the Sierras, as this diagram indicates, and there is no point known to the writer where, south of the latitude of San Francisco, the precipitation on the western slopes of the Sierra Nevada approaches 80 in. per annum, as shown by the curves of this diagram.

The same suggestion applies to the run-off diagram, Fig. 16. Dependence on the curves there shown, particularly for the Sierra Nevada eastward from San Francisco, might lead to disappointment.

As a contribution to the rainfall and run-off information in the San Francisco Bay region there is submitted herewith the result of a study made by the writer several years ago.

The run-off curves on Plate I will show at a glance the limit of the water crop at any point under consideration. Where, as in the case of the Crystal Springs reservoir of the Spring Valley Water Company, the storage capacity is so large that practically no water goes to waste, the run-off shown by the curves, less the loss from the reservoir by evaporation and seepage, will determine its productiveness. The curves afford a quick first approximation of the possible limit of yield.

The frequency of years of heavy, moderate, and light rainfall in the vicinity of San Francisco are shown by Fig. 27. The rainfall is expressed as a percentage of the normal annual rain in order to give the diagram wider use than just for the locality for which prepared. These data can readily be fitted into a probability diagram to obtain departure from the ordinary law by any one interested in this climatic peculiarity.

*The writer is sorry that what he stated in the foregoing discussion should have been construed as a reflection either on the course taken by the City Engineer of San Francisco in calling for a board of consulting engineers, or by these engineers who are defending themselves against a fancied imputation of being political engineers. The writer has been on the best of terms with each of these engineers; they have his unqualified respect and confidence; and he would not intentionally have said anything to their discredit. His only purpose in referring to the appointment of consulting engineers was to show that no intention was apparent on the part of the present administration to create a Water Board, and that the present plan of managing municipally owned utilities would probably be continued.

* The following part of Mr. Grunsky's discussion was written after reading Mr. O'Shaughnessy's discussion.

Mr. Grunsky.

The statements from the writer's earlier discussion, which are objected to, and which have been quoted, should be read in connection with the following which was a part thereof:

"Nevertheless, the danger should be recognized that competent management of to-day under the political system may be followed by incompetent or even corrupt management to-morrow."

Neither in this statement, nor in a preceding use of the term "political", is there any intent to cast an unfavorable reflection on those who happen to occupy official positions. The instability of their tenure of office, however, is self-evident, and the large number of depart-

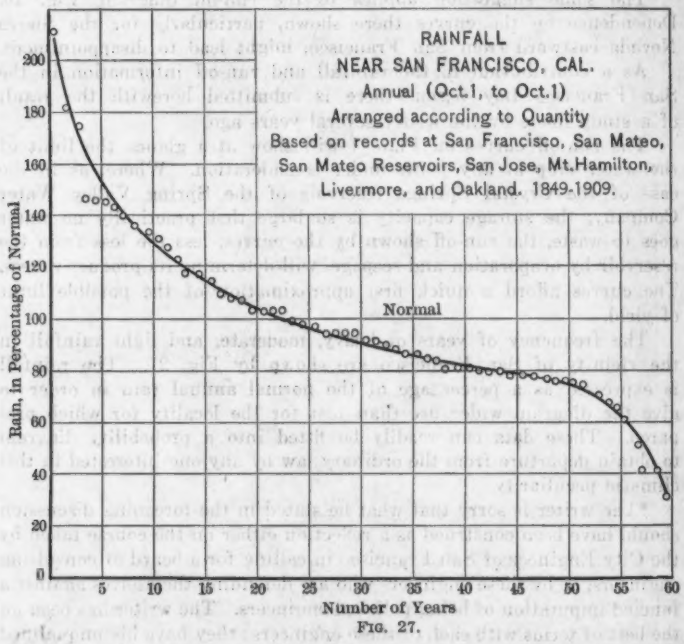

FIG. 27.

ments or sub-departments of the City's Government which have been and are assisting in directing the acquisition of a municipal water supply, and will have a voice in its management, condemn the system. No evidence is yet apparent that the creation of a stable Water Board is under contemplation, and it was to show this fact, and for this purpose only, that reference was made to the appointment of a board of engineers by the City at the request of the City Engineer. The writer agrees with those who state that it was better to have the con-

sulting engineers selected by the City Engineer, who understands the problems to be passed on, than to have left their selection to other City officials. Mr. Grunsky.

The writer believes the *Transactions* should not be burdened with a reply to the personalities contained in the discussion by Mr. O'Shaughnessy.

WILLIAM SCHUYLER POST,* ASSOC. M. AM. SOC. C. E. (by letter).—This paper is an inspiration. It indicates to the engineer a legitimate field which he has abandoned and left to the cultivation of promoters and chambers of commerce. All have smiled at the vagaries of the western "booster", and admitted that people were fools to believe; but we have "stood for it", and have not realized that here is a real science of economic importance, one which the engineer is competent to pass on, and which he should pass on—the assigning of values to elements of civic growth, assigning weights to these values, and making a logical deduction from the known to the predicted. Mr. Post.

It is an ordinary platitude that a city must look 50 years ahead in its water supply. The simple matter of width of streets is left to the accident of original dedication. The cost of future congested traffic and the economic wastes of inadequate or over-adequate present construction and planning all belong to a group which invites the intellectual and imaginative qualifications of the engineer, wherein, working in the present, he foresees, provides for, and harmonizes, the economic situation a decade or more beyond.

As an Angeleno, and with a more or less profound geologic knowledge, the writer cannot admit that the San Francisco fault line runs near Los Angeles. In fact, he believes that the nearest active fault is 60 miles distant, and earthquake disturbance is in reality negligible in Los Angeles. However, the writer enjoys admitting that the eastern colonist puts all California in the earthquake class, and balances it in his mind with cyclones in the Middle West. Therefore, as far as the psychology of the colonist is concerned, before he starts for the coast, the conclusion of Reason 12 is sound; and therein lies the interest of such investigations as these.

M. M. O'SHAUGHNESSY,† M. AM. SOC. C. E. (by letter).—The writer has read this paper carefully and confesses himself embarrassed to analyze its motive and value. There has been much discussion in recent years as to the various fields in which the engineer may become active, outside of the exercise of his profession as such, and Mr. Cory's paper certainly invades many foreign subjects into which it has never been even suggested that the engineer should inject himself. Mr. O'Shaughnessy.

Mr. Cory enters into a discussion of political, sociological, moral, economic, and financial features of a great and varied State, and all

* San Diego, Cal.
† San Francisco, Cal.

Mr. O'Shaughnessy.

the sub-divisions thereof, and it is to be feared that he is so enthusiastic in those realms that he neglects the engineering side of the problem.

One of the earliest precepts instilled into the minds of young engineers, both before and after their entrance into the practice of their Profession, is the necessity of obtaining as exact information as possible on a given subject before proceeding with any independent work thereon. It is evident, however, that this precept has been, to some extent at least, disregarded in the present case, as some of the author's statements are only partly true, and others, so far as the knowledge of the writer goes, are not true at all.

The paper consists chiefly of a résumé of matters which were thoroughly and scientifically discussed and settled at the time the grant of the Hetch Hetchy reservoir sites, rights of way, etc., to the City of San Francisco was under investigation by Federal Government and other experts.

Mr. Cory attempts to revive a number of dead issues, and questions the engineering and financial policies of San Francisco as if these matters had not already been thoroughly considered and disposed of by a number of distinguished engineers, whose names are recognized throughout the United States—and throughout the civilized world—as authorities in their respective fields of work.

The Hetch Hetchy project has been the subject of a vast amount of painstaking thought and labor on the part of the officials of San Francisco and the experts whose advice was sought by them. The people of the City understand the situation of the municipality with regard to the water supply, and are as thoroughly in accord on the Hetch Hetchy scheme at the present time as they showed themselves to be some years ago, when propositions to bond the City for the acquisition of lands and for the construction of the works were carried by a vote of six to one.

The City has offered the neighboring East Bay communities—Oakland, Berkeley, Alameda, and the smaller cities—every opportunity to join with her in obtaining a mountain water supply. These cities naturally form a part of a Metropolitan District the interests of which will be best served in co-operating with the project of San Francisco. Up to the present time all the Bay cities have been furnished with water by private corporations. For years, the Spring Valley Water Company of San Francisco bitterly fought the acquirement by the City of rights in the Hetch Hetchy region, and by a skilfully planned propaganda created very strong opposition to the City among the irrigationists whose lands are contiguous to the Tuolumne River. This corporation opposition did not cease until the Raker Bill was passed.

The City officials have since agreed with the Company on a purchase price for its property, and this is to be submitted to the voters

for ratification at a special election in March, 1915. There is some opposition to the proposal, based on the idea that instead of buying the Spring Valley properties at a price which those opposing the plan consider excessive, the City should proceed at once to the construction of a Hetch Hetchy system, and rely entirely on this source, independent of the existing works of the Spring Valley. The opposition from the irrigation districts to the Hetch Hetchy scheme was modified on the inclusion of conditions, in the Raker Bill, which guarantee to the irrigationists their developed rights and a much larger quantity of water than they were technically entitled to under the State laws for 60 days of the flood period of each year; thus, there is no longer any serious opposition to the Hetch Hetchy project from any faction in San Francisco or in the San Joaquin Valley, except from some irreconcilable agitators. Mr. O'Shaughnessy.

The people of the transbay cities generally favor uniting with San Francisco to form a water district, and such opposition as now exists in those communities has been stirred up by the Peoples Water Company, which is in financial turmoil from imprudent high financing. This Company made futile opposition to the Raker Bill. Its only hope for survival is to keep its customers out of the proposed Metropolitan Water District.

Such is the general situation of the San Francisco Bay region with regard to the mountain water supply. The question of necessity has been settled; the Hetch Hetchy has been found to be the most available source of supply by a board of distinguished and disinterested army engineers, either for San Francisco alone, or for the proposed water district. San Francisco, without waiting for the formation of the Metropolitan Water District, has already begun construction work in the Hetch Hetchy region.

The writer cannot see in what respects the matters touched on by this paper are of sufficient interest to the engineering world to justify its publication by the Society; but, as it has been published, he will, without attempting to reply to it in detail, indicate a few points on which he takes issue with the author.

First, as to competition between the San Francisco Bay cities and Los Angeles: The Bay cities do not regard themselves as competitors of Los Angeles. This statement must not be taken as a confirmation of Mr. Cory's idea that San Francisco is self-sufficient. It means that San Francisco recognizes her southern neighbor's place in the general scheme of things; that the interests of the two cities are dissimilar; that the prosperity of one is helpful to the prosperity of the other; and that San Francisco realizes that increased prosperity in Southern California benefits the State as a whole.

However this may be, competition or non-competition between the Bay cities and Los Angeles could not be a factor in determining

Mr. O'Shaughnessy.

the choice of a water supply. Conditions are so different in the two sections of the State that a matter of such small import as the annual water bill could cause little difference to any one who is making his choice of a permanent home, or be a final factor in determining the moral status or commercial triumph of either city. The comparison of sociological conditions in the two communities is no part of an engineering problem. However, personal knowledge and civic pride impels the writer to correct a few statements in Mr. Cory's comparison, which are either wholly or partly incorrect.

In a comparison of growth, on page 8, the growth of the San Francisco Metropolitan District from 1900 to 1910 is given as 41 per cent. Referring to the Abstract of the 1910 Census, page 62, it is found that the figure should be 45.2 per cent. A comparison of the population curves, Fig. 2, with the figures of the Census on page 62 of the Abstract, shows that in Fig. 2 the population of "Greater San Francisco-Oakland" in 1900 is 25 000 less than the Census figure, and in 1910, 60 000 less; the population of "Greater Los Angeles" in 1910 as plotted is 30 000 less than the Census figure. These discrepancies are not very large, but they work against the northern cities. Furthermore, any comparison between the growth of San Francisco and that of Los Angeles since 1900 must take into account the retardation of San Francisco's growth by the disaster of 1906 and the great apparent acceleration of that of Los Angeles due to the annexation of a number of small cities and towns in the outlying districts.

On page 17, it is stated that the San Francisco port charges and regulations are onerous. Referring to a paper by H. M. Chittenden, M. Am. Soc. C. E., entitled "Ports of the Pacific",* the writer would call attention to Table 6, "Comparative Costs to Ship and Cargo in Pacific Coast Ports", and quote from the note at the end of that table:

"This table is the result of a comparative study of the rates in the different ports with a view of determining the relative tax on commerce in each. In order to arrive at a condensed approximation of the cost of terminal charges and a comparison of the principal Pacific Coast ports, a purely hypothetic case has been assumed of a 6 000 net ton register ship, 30-ft. draft, discharging and loading cargoes of 12 000 tons of miscellaneous freight, the ship remaining in port 12 days."

The total cost to ship and cargo in the various ports is shown in Table 7, from which it will be seen that the cost paid by the ship is three times as great at San Francisco as at Los Angeles; the cost paid by the cargo at San Francisco is 79% of that at Los Angeles; and the cost paid by the ship is so small a part of the total cost that the total cost at San Francisco is less than 84% of that at Los Angeles.

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 208.

Furthermore, Table 7 shows the total cost at San Francisco to be lower than at any of the other five ports mentioned. It is immaterial to both the shipper and the ultimate consumer how the port charges are divided, for that which interests them is the total amount they have to pay. Mr. O'Shaughnessy.

TABLE 7.

	Total cost.	Cost paid by ship.	Cost paid by cargo.
San Francisco	$18 042.50	$1 242	$16 800.50
Los Angeles	21 599.00	407	21 192.00
San Diego	22 475.00	875	21 600.00
Portland	22 280.00	680	21 600.00
Puget Sound	21 800.00	200	21 600.00
Vancouver, B. C.	21 830.00	230	21 600.00

The term, "Paris of America", applied by the author to San Francisco, is an echo from a political campaign of a few years ago. It was first used in reference to some proposed system of municipal improvements which should make San Francisco the most beautiful city in America and a pleasure resort for the whole continent, but was later turned to the derogatory sense in which it appears in the paper. It died with the campaign, and it is not fair to use such casual expressions in a comparison of the solid merits and achievements of cities.

As to the 2 200 saloons in San Francisco, the Police Commission of San Francisco gives the number of retail liquor licenses now in force as 2 051, which includes some hundreds of restaurants where liquor is sold with meals.

The civic spirit of San Francisco is manifested in the attitude of the people toward public improvements. When shown the necessity or advisability of such works, they have been most liberal in voting bonds, although showing great intelligence and discrimination in demanding proof of the advantage to come from proposed expenditures. A great amount of money has been spent during the past ten years, and more is now being spent, on improvements the cost of which is approximately as follows:

New sewer system, nearly complete	$6 150 000
High-pressure fire system, acknowledged by all experts to be the best in the world, containing 72 miles of mains, covering all the principal business and residence districts, and reducing the insurance rates annually $1 250 000	5 750 000
Municipal street railways, 25 miles of double track, with rolling stock and car barns	5 500 000
Carried forward	$17 400 000

Mr. O'Shaughnessy.

Brought forward	$17 400 000
Asphalt plant	60 000
Civic center	8 800 000
Schools	7 500 000
Hospitals	3 000 000
Fire and police stations	510 000
Public library lands	740 000
Hall of Justice and County Jail	1 350 000
Hetch Hetchy water supply, lands and preliminary work	2 000 000
Docks	9 000 000
Streets and pavements	15 000 000
New parks and public playgrounds	1 360 000
Traffic tunnels	4 600 000
Total	$71 320 000

In addition to these municipal enterprises, about $11 000 000 has been expended on the Panama-Pacific International Exposition, the total expenditures on which will amount to about $18 000 000. Of this amount $7 500 000 was subscribed by corporations and individual citizens of San Francisco, and $5 000 000 was raised by the issue of municipal bonds.

The total amount of municipal bonds sold during the past ten years is $47 701 200. The City's bonds have generally commanded premiums, so that the total amount of money realized was about $49 253 000. The total amount authorized by the voters, but not yet sold, is $45 832 800, which includes $43 428 000 for the Hetch Hetchy water supply. The harbor bonds are a State issue, to which the citizens of the State contribute nothing, as the interest and sinking-fund payments come from the port revenues. The difference between the total cost of improvements mentioned and the total amount of bonds sold is accounted for by premiums on bonds and by payments for work out of current revenues and by assessment districts.

The municipal street railways constitute the first essay of San Francisco in the municipal ownership of public utilities, and the results are very gratifying. The first line was opened to traffic on December 28th, 1912, and at present there are 18 miles of double-track railways in operation, 4.5 miles under construction, and 2.5 miles being planned. The gross receipts during August, 1914, averaged $3 186 per day, and the operating expenses, $1 597 per day. The amount invested in the roads now in operation is about $4 000 000, on which the interest charge is about $525 per day. Liability insurance costs about $45 per day. Depreciation is estimated at 18% of the gross receipts, or $573 per day. The total daily expenses of the roads thus amount to $2 740, leaving a balance of $446 per day,

Mr. O'Shaughnessy.

which is a rate of more than $160 000 per year, or 4% of the investment—much more than the amount of the taxes that a private corporation would pay—available to be applied to extensions of the lines. This augurs well for the City's ability to manage successfully its own water system and the accompanying power development. Incidentally, it may be mentioned that San Francisco is the first city in America to achieve financial success in the operation of a municipally owned street railway system.

The writer apologizes for having taken up so much space with matter entirely irrelevant to the subject in hand, his excuse being that he wishes to correct any misapprehensions which might become fixed in the minds of the readers of the paper, if the statements contained therein were permitted to go uncorrected.

As to the water supply situation in the Bay cities, Mr. Cory presents considerable discussion on the present and possible future sources for San Francisco, beginning with the Spring Valley Water Company's system. For years there has been much investigation as to both the ultimate and the available yield of the Spring Valley sources. Many reports and estimates have been filed by various parties—some representing San Francisco or the East Bay cities, or both; others working in the interests of one or more of the water companies supplying those cities. In matters of this sort it usually happens that investigators of the latter class are very optimistic in their estimates, and those of the former class are more conservative. Table 1 shows the estimated yield of the various Spring Valley sources. The grand total yield of the Water Company's Peninsular and Alameda systems is estimated by Messrs. Herrmann, Schussler, Chittenden, and Powell, at about 220 000 000 gal. per day. These engineers were all engaged on the Spring Valley side of the controversy before the Secretary of the Interior regarding the City's proposed Hetch Hetchy development. Their estimates were reduced 50% by the U. S. Army Engineers, and, furthermore, it was shown that the yield was not obtainable, except at prohibitive cost, for municipal purposes. Mr. Dockweiler, representing the City in the same case, in his American-Cosumnes report, gave an estimate, also shown in Table 1, of 109 500 000 gal. per day—about half the amount of the estimates of the engineers on the other side. Later investigations prove even this to be excessive.

The run-off and discharge records mentioned by Mr. Cory on page 32 are not by any means all that could be expected of run-off and discharge records. Those on Calaveras Creek consist mainly of a series of records of depth and width and crude float observations over a very short course, taken by a watchman. No serious attempt at scientific stream gauging has been made until very recently. Members of the staff of the City Engineer of San Francisco, with the co-operation of the Spring Valley Water Company, are now making such

Mr. O'Shaughnessy.

measurements of stream flow from the Company's sources as will make possible more precise estimates of the possible water development from those sources than can be made at present from the rough and ready measurements of the past.

The same degree of uncertainty which exists with regard to the Spring Valley sources, and the same wide variation of estimates of possible yield, are encountered in the study of the sources from which the transbay cities draw their water supply. The situation in Alameda County is complicated further by the fact that the various streams, the water of which it is proposed to take for domestic supply, are the same streams that replenish the underground water supply of the valleys below, and any further withdrawal of water, beyond the quantities now taken, will be bitterly opposed by the farmers who use the underground supply for irrigation.

Yet, Mr. Cory, unmindful of the differences between engineers who have made long and careful study of the various sources, and not heeding the possible legal complications, states positively on page 36 that the total ultimate safe draft for municipal purposes for San Francisco and the Peninsula, the East Bay region, and Marin County and the North Bay region is 231 000 000 to 256 000 000 gal. per day, allowing a variation from minimum to maximum of only 25 000 000 gal.

It is certainly absurd for any one to assume that the engineers for the Bay cities have not given thorough investigation and consideration to the possibilities of the local sources of supply. In doing so they have analyzed all phases of the question, and have given due weight to inaccuracy of records and possible legal complications, and also to the fact that the development of some portions of the local sources would be so costly as to be prohibitive, unless there was absolutely no other available source.

For example, the coast streams of the Spring Valley Water Company were credited by Mr. Dockweiler, in his American-Cosumnes report, with a yield of 31 700 000 gal. per day, but to develop this water would be so expensive that ordinary financial prudence would demand that the money be used toward the development of the large supply, at less cost, which it is ultimately proposed to bring from the Sierra Nevada.

It is clear, to those who have investigated the situation from a fair and impartial standpoint, that the supply which can be developed economically from the local sources will be scarcely more than sufficient to keep pace with the normal growth of the cities and the suburban communities tributary thereto until the mountain water can be introduced.

Whether the problem is one for San Francisco or for "Greater San Francisco-Oakland", the answer is that San Francisco and Oakland

Mr. O'Shaughnessy.

are both "in the same boat" as regards water supply; both need immediate extensions, both are suffering from the exploitation of private speculative corporations, and San Francisco would welcome the co-operation of Oakland in the development of her water supply; but, if Oakland does not decide to assist, San Francisco must, of necessity, go ahead by herself.

Under the discussion of whether "Greater San Francisco-Oakland" can afford a Sierra supply, Mr. Cory, on page 39, asks: "Can San Francisco afford the luxury of a Sierra water supply at an immediate expense of more than 10% * * * of its present assessed valuation?" (The present assessed valuation is $646 700 065.) Also, on page 78, he states: "The City has revised the estimated cost of the first 160 000 000 gal. per day installation from Mr. Freeman's figure of $37 501 400 to $64 000 000, and probably the figures on the other installations as well."

The writer is at a loss to understand these statements. Mr. Freeman's estimate of the total cost of the initial installation, not including the cost of a city distributing system and the permanent power development, is given on page 160o of his published report of July, 1912:*

> "Total cost of supply, varying from maximum of 240 million gallons daily to minimum of 160 million gallons daily in extreme drought, delivered to Irvington gate house overlooking San Francisco Bay, with 50 millions delivered into San Francisco 3 miles from City Hall, and 50 millions into Crystal Springs Reservoir when desired.... $36 981 000
> "And also with 60 million gallons daily ready for Oakland, San Jose, etc."

Mr. Freeman's estimate of $36 981 000 (not $37 501 400), on the basis given by him, still stands. Thus far, no radical departure from the Freeman plans is proposed, except that it may be considered advisable to install initially a smaller pipe line, 45 miles long, across the San Joaquin Valley for a supply of 60 000 000 gal. per day, and to develop at once 50 000 hydro-electric horse-power. The cost developed by Mr. Freeman was based on the assumption that common labor will be paid a rate of $2.25 per day of 8 hours. The Charter of San Francisco requires that common labor be paid $3 per day on municipal work. It is still an open question whether this rate will be held to apply to all work outside of the City as well as that within the City limits. If it should be so, the effect will be to increase the cost of the whole project perhaps 20%, bringing the cost of the system, if built according to the Freeman plans, to about $45 000 000. (These figures do not include a city distributing system.)

* "The Hetch Hetchy Water Supply for San Francisco, 1912: Report."

Mr. O'Shaughnessy.

On page 78 the statement occurs: "There are about 100 miles of steel pipe, some of it under heads as high as 600 to 900 ft." This is erroneous, as the Hetch Hetchy aqueduct, in the Freeman plans, from the Early Intake to San Francisco, contains 66 miles of tunnel and 87 miles of pipe. The highest head (except in the penstocks of the power-houses) is near Oakdale, at the east end of the San Joaquin Valley crossing, and is considerably less than 600 ft. Mr. Cory is in error here.

In calculating on other sources of water supply, the same prices of labor and material were used as in the estimate of cost of the Hetch Hetchy scheme, with the exception of the estimate for the filtered supply from the Sacramento River, in which Mr. Hazen used $3 per day of 8 hours as the wages of common labor. Thus, the question of unit prices does not enter into the comparison of various sources.

This matter was thoroughly understood by the Board of U. S. Army Engineers which acted in an advisory capacity to the Secretary of the Interior regarding the grant of the reservoir sites and aqueduct rights of way. The members of this Board were selected as competent and impartial judges, and not only compared the estimates submitted to them, but made their own independent estimates on the same basis. These covered nearly all the possible sources mentioned by Mr. Cory on pages 62 to 76, including Coast Range sources, supplies from the delta of the Sacramento and San Joaquin Rivers, and Sierra sources from the McCloud River to the Tuolumne. They heard or read all the testimony submitted by the City of San Francisco, the Spring Valley Water Company, and promoters interested in various possible competing sources of supply, and confirmed the judgment of the City's engineers that, considering the problem from the standpoints of both engineering and economics, the Hetch Hetchy is the most desirable. To quote their own words, from page 50:*

"The project proposed by the City of San Francisco, known as the Hetch Hetchy project, is about $20 000 000 cheaper than any other feasible project for furnishing an adequate supply."

Relative to this matter, the following extract, from page 14 of that report, is of interest:

"In one important respect the situation in California requires special consideration. * * * In California all water has great value. Due to the large extent of arid and semiarid land that can be made fertile by the use of water, irrigation is assuming great importance; due to lack of coal and the opportunity for economical water-power development the use for the latter purpose will surely be greatly extended. In a relatively few years practically all available water will doubtless be appropriated for one or the other purpose,

* "Hetch Hetchy Valley: Report of Advisory Board of Army Engineers to the Secretary of the Interior," February 19th, 1913.

and it will then be possible to obtain it for municipal use only at great cost and damage to existing communities and industries. It is, therefore, necessary to-day for the cities of California to look further ahead than in most other parts of the country, and to take such steps that in the future when they may need the water they shall have the right to it. For this reason it is believed that in making provision for the future supply of San Francisco and other bay cities a source should be selected if possible that is capable of supplying the needs of the communities for the balance of this century. Such a course would seem both wise and reasonable, provided it involves no sacrifice of economy." Mr. O'Shaughnessy.

This answers the question as to whether or not the Bay cities can afford a Sierra supply. Their material, social, and commercial development depends on their obtaining additional water; the Hetch Hetchy has been shown to be the most economical and adequate source; and between the alternatives of providing additional pure water supply by the community or civic stagnation under existing conditions, there can be but one answer to the question.

The Raker Bill, which grants to San Francisco the necessary reservoir sites and aqueduct rights of way through the public lands, was a compromise between the conditions on which the City first sought the necessary rights for the development of the Hetch Hetchy water supply, and those which the irrigationists sought to impose. In framing the bill due regard was also given to the consideration that the National Park should not be treated in any way that would detract from its status as a pleasure ground for the public. A great deal of thought was devoted to the formulation of this bill by the City's engineers and attorneys, who did not wish at any time to take from the irrigationists any water that they might usefully apply to their lands and be legally entitled to. The City has always realized that its prosperity and that of its back country are to a large extent mutually dependent, and, further, does not wish to antagonize the irrigation districts by taking from them something which they feel belongs to them. The demands of the irrigationists have been increased several times since the City made its initial application to the Secretary of the Interior, and the final result was that the City consented to the practical guaranty that the irrigationists should have water to the extent now legally diverted by them in their two canals, Turlock and Modesto, namely, the full natural flow of the Tuolumne and its tributaries up to 2 350 sec-ft. at La Grange diverting dam when the districts can beneficially use it, and 4 000 sec-ft. from April 15th to June 14th of each year.

This arrangement, however, was only consented to after the City's engineers had thoroughly investigated the available water supply of the Tuolumne, revised their former figures, and found that, even with

Mr. O'Shaughnessy.

the restrictions imposed, there would still be sufficient water to fulfill the conditions and leave the City's own future supply up to 400 000 000 gal. daily for domestic purposes unimpaired. In confirmation of this, the following finding of the Army Board is conclusive:

"The board is of the opinion that the use of the Hetch Hetchy Valley as a reservoir site is necessary if the full flow of the upper Tuolumne is to be conserved.

"The board further believes that there will be sufficient water if adequately stored and economically used to supply both the reasonable demand of the bay communities and the reasonable needs of the Turlock-Modesto Irrigation District for the remainder of this century."

The Raker Bill, as passed, has been reviewed by Mr. Freeman, who was one of the principal consulting engineers for the City. On March 21st, 1914, he submitted a report to the City Attorney and the City Engineer entitled, "Reservoirs Ultimately Required for a Hetch Hetchy Water Supply of 400 Million Gallons Daily for San Francisco under the Terms of the Raker Bill". The following is quoted from that report:

"I submit herewith my report upon the additional burden imposed upon the City of San Francisco by increased water rights given to the irrigation districts by the terms of the recent grant by Congress to the City of San Francisco, of rights of way and reservoir sites in the Hetch Hetchy region, by House Bill No. 7207, known as 'The Raker Bill'. I am pleased to report that a most painstaking study proves that the City can never suffer seriously from this cause, and the conclusion is justified anew, that it was ten-fold better for the City to make these concessions than to imperil the passage of the Hetch Hetchy bill, and that the total storage of 190 billion gallons, or say in round numbers, 200 billion gallons, found necessary for a dependable water supply of 400 million gallons daily in a series of years of lowest rainfall ever yet known, by my new computations, can be had in the City's three reservoir sites, Hetchy, Eleanor, and Cherry, with the addition of Vernon Lake and Poopenaut.

"Altho the terms of the grant are now fixed beyond change, it has appeared wise to check up the hurried computations made while the Bill was being negotiated before Congressional committees last Summer and review all data in the most painstaking way, particularly since the wisdom of certain conclusions reached by the City's representatives has been questioned by certain good citizens before one of your most important civic organizations, and also because there is now available the daily record of gagings at the City's dam sites at Hetchy and Eleanor thruout the remarkable severe drought of 1912-1913, to which the priorities specified in the Raker Bill can be directly applied, affording a more variable and convincing demonstration."

The additional burden on the City, due to the terms of the bill, is seen from this report to be merely a matter of constructing some

Mr. O'Shaughnessy.

comparatively small and inexpensive reservoirs in addition to the Hetch Hetchy, Eleanor, and Cherry Reservoirs, which have been contemplated all along.

There are reservoir sites available to San Francisco and to the irrigation districts, with capacities which total much more than the maximum storage which will ever be required.

The Raker Bill sets aside for the use of the City all reservoir sites above the mouth of Jawbone Creek (a tributary entering the main Tuolumne River about 15 miles below the Hetch Hetchy dam site), leaving the irrigationists the right to develop storage below that point. The following reservoir sites are thus available for San Francisco:

	Capacity, in acre-feet.
Hetch Hetchy Valley (300-ft. dam)	344 000
Lake Eleanor (250-ft. dam)	288 800
(Mr. Freeman figures on a 150-ft. dam giving 37 000 000 000 gallons or 113 500 acre-ft. capacity.)	
Cherry Valley (150-ft. dam)	56 800
Vernon Lake	47 900
Wilmer Lake	5 000
Tilden Lake	27 800
Emigrant Lake	14 300
Huckleberry Lake	52 200
Poopenaut Valley	44 300
Cherry Mouth (at junction of Tuolumne and Cherry Rivers)	8 200
Total	889 300

or 290 000 000 000 gal., which is 90 000 000 000 gal. more than is necessary, in Mr. Freeman's opinion, as previously quoted, for the City's development of 400 000 000 gal. per day.

Below Jawbone Creek, and contiguous to the Tuolumne water-shed, the following sites remain:

	Capacity, in acre-feet.
Empire Mills Reservoir site	35 000
Coffin Hollow	12 000
Lily Lake	15 000
Cottonwood	25 000
Ackerson	26 000
Stone	26 000
Fernbrook	26 000
Heardin	25 000
Carried forward	190 000

Mr. O'Shaughnessy.

	Capacity, in acre-feet.
Brought forward	190 000
Big Creek	12 500
Moccasin Creek	12 000
Upper La Grange	200 000
Dry Creek	325 000
Davis Reservoir (already constructed)	48 000
Dickinson Reservoir	60 000
Dallas and Warner Lakes (storage of 30 000 acre-ft. already developed)	60 000
Total	907 500

or 296 000 000 000 gal.

All these reservoir sites, with the possible exception of a few of the smallest, are capable of development at an economical cost per acre-foot stored.

Pending the construction of additional reservoirs by the irrigation districts, the Raker Bill provides that whenever the districts desire water in excess of that to which they are entitled under the terms of the bill, the City, on the demand of the districts, shall sell such quantities of stored water as may be needed for the beneficial use of the districts—without impairing the supply for domestic requirements—at such a price as will return to the City the actual total cost of providing such stored water, including a fair proportion of the cost to the City of the conduit, lands, dams, and water-supply system included in the Hetch Hetchy and Lake Eleanor sites. It is provided, however, that the City may require the irrigation districts to purchase a minimum quantity of stored water, and shall not be required to furnish more than a maximum quantity, in any calendar year, the minimum and maximum quantities to be fixed by the Secretary of the Interior, keeping in mind the superior needs of domestic use; and, further, the City is not to be required to furnish more than the minimum quantity until the districts shall have first drawn on their own stored water to the fullest practicable extent.

No hardship on the City is to be apprehended from the obligation under these terms to furnish water to the irrigationists. The latter have already developed storage amounting to 78 000 acre-ft., which is capable of expansion, as already shown, to a final total of more than 900 000 acre-ft. Their dams and appurtenances are not and need not be of the relatively expensive type required for the purposes of a domestic water supply, and, therefore, the provision that the water purchased by them shall be paid for at a price which will include a fair allowance for the cost of construction should certainly induce them to construct their own reservoirs.

Mr. O'Shaughnessy.

Furthermore, the irrigation districts have the option to purchase surplus electric power which the City may not need, for the use of any land owner or owners therein for pumping sub-surface water for drainage or irrigation at cost. This will make economically available to the irrigators the vast underground water supply which lies only a few feet beneath the ground surface but is as yet practically untouched, owing to the prohibitive cost of steam power in small units and electric power purchased from corporations whose prices include the profits of their stockholders.

The districts have already spent considerable money in efforts at drainage of sub-surface water due to the rising of the ground-water from over-irrigation, and a generous supply of power to aid them in this policy will far outweigh any sentimental objections to San Francisco's storage of waste flood-waters on the higher mountain levels.

It is not within the range of probability that if during any year the City's supply of stored water should be brought so low as to make a water famine imminent, she should still be compelled to furnish water to the districts, particularly if they had not used the same diligence in developing the reservoir sites available to them that would be expected of the City both under the terms of the Raker Bill and under the dictates of ordinary foresight and prudence.

Turning now to the conclusions on pages 85 to 87, the writer will endeavor to answer, from the standpoint of a citizen of San Francisco and, to the best of his ability, from the standpoint of a citizen of the proposed Metropolitan District as a whole, the questions that Mr. Cory propounds to the citizens of San Francisco.

The cities of the Metropolitan District should naturally develop together, and all the cities concerned are facing a shortage of water; their development depends on their securing an additional supply at once; their interests are interwoven—the problem of supply is certainly one for a metropolitan water district to handle.

As already stated, San Francisco has attempted to get the transbay cities interested with her in securing additional water supply. Due doubtless to the selfish interests at work, those cities have not yet responded to San Francisco's invitation. There is little doubt, however, that they will eventually do so. It happens, however, that the most available source of supply for the Metropolitan District is also the most available source for San Francisco alone, and as the demand for additional water is on us, San Francisco must proceed independently with her development, until such time as the transbay cities may see fit to enter into the work and share the burden with her.

The studies which have been carried on during the past few years have convinced the City's engineers that the economically available increase of the water supply from the Spring Valley sources is hardly more than sufficient to cover the present unsatisfied demand and the

Mr. O'Shaughnessy.

natural increase of consumption during the period of construction of the Hetch Hetchy works.

The Hetch Hetchy scheme has been the subject of very serious consideration by many engineers who, after comparing it with all other available sources of water supply, have endorsed it. The engineers who have questioned it, with the sole exception of those employed by the irrigation districts, have been the representatives of special competing interests, hoping to dispose of their own private holdings for their own private gains. The Raker Bill, as passed, imposes on the City a slight additional burden to that which it has always expected to sustain, in the form of obligations not to interfere with the developed water supply of the irrigation districts, and the City, by consenting to the conditions of the bill, has eliminated the unjust accusation that she was trying to gain something at the expense of the irrigationists.

The securing of the Hetch Hetchy water supply is not a matter of sentiment with the people of San Francisco in the limited sense in which the word "sentiment" is used by Mr. Cory. The sentiment of the people is for the development of their City. Their accredited representatives have shown, to their satisfaction, that the Hetch Hetchy is the best source of water supply available, and they are willing to invest in it, not "sums so vast that many other requirements more vital to the interest of the City must be sacrificed or skimped", but the reasonable and necessary cost to secure the water supply which is essential to the growth of the City and the expansion of its enterprises.

The acquisition of the present water systems of San Francisco and of the Bay cities, either by a Metropolitan District, or, pending the formation of such a district, by the cities acting independently, is a very desirable step toward the development of a well-balanced metropolitan system.

Mr. Grunsky,* in his discussion, states correctly that in Mr. Cory's paper there is a marked departure from the ordinary treatment by an engineer of an engineering problem. At and previous to the time the paper was prepared its author had never been officially employed on an investigation of the subject therein discussed. It is therefore natural that any engineering data presented should be merely a résumé of the studies of other investigators, and since no new light is thrown on the subject, the matter therein is of little importance to the Profession at large. Mr. Grunsky, however, as noted in his discussion, held the position of City Engineer of San Francisco from 1900 to 1904. As the former occupancy of that office lends weight

* The following part of Mr. O'Shaughnessy's discussion was written after reading the discussion by Mr. Grunsky.

to his statements on the water question, it is necessary that some of the erroneous impressions conveyed by his discussion be corrected. Mr. O'Shaughnessy.

Mr. Grunsky calls attention to the fact that the Hetch Hetchy project under the Raker Bill is not his Hetch Hetchy project. Despite Mr. Grunsky's best efforts, his application, filed in 1901 with the Secretary of the Interior, for a permit to impound water at Hetch Hetchy and Lake Eleanor and conduct 60 000 000 gal. daily to the City was denied. In 1905 the application was renewed, but permission was again refused.

In 1908 Secretary Garfield issued a revokable permit allowing the construction of the Eleanor Dam as a first unit of construction, but requiring the full development of the Lake Eleanor water-shed before any work could be done in the Hetch Hetchy Valley. Only 79 sq. miles of water-shed are tributary to the Eleanor Dam site, on which a dam, 1 700 ft. long on the crest, would have to be constructed to impound a run-off of only 20 billion gallons in ordinary seasons, and in years of minimum precipitation 8.7 billion gallons. In contrast, the area tributary to the Hetch Hetchy dam site is 459 sq. miles, or 5½ times that of Lake Eleanor, and a dam 300 ft. high and 700 ft. long will impound 112 billion gallons. The Eleanor Dam site is much more inaccessible than the Hetch Hetchy, and unit prices for construction materials delivered would be correspondingly greater. Despite the fact that the Garfield permit would require a vastly greater initial expenditure to develop far less water, and after the City had voted $45 000 000 for constructing the Hetch Hetchy-Lake Eleanor system, in February, 1910, Secretary Ballinger called on San Francisco to show cause why the Hetch Hetchy Valley and reservoir site should not be permanently denied San Francisco and eliminated from the above permit. After fighting for nine years, the City had nothing tangible to show for the money it had expended. Then, to quote Mr. Grunsky:

"San Francisco was thus put on the defensive and, due to lack of confidence of various of her official departments in each other, placed this case in the hands of an expert called in from the East."

This expert, of whose employment Mr. Grunsky declares with some bitterness "the natural result was that thousands of dollars were needlessly expended in the accumulation of a mass of statistical information", was John R. Freeman, M. Am. Soc. C. E., whose masterly presentation of accurate statistical information on this project to the Board of Army Engineers was one of the most potent factors in securing for San Francisco the Hetch Hetchy grant. The subsequent report rendered to the Secretary of the Interior by the Board of Army Engineers substantiated practically every claim made by Mr. Freeman. Mr. Freeman's report, augmented by the oral testi-

Mr. O'Shaughnessy.

mony of the City Engineer of San Francisco, Percy V. Long, City Attorney, and Colonels Biddle, Cosby, and Taylor, who constituted the Advisory Board of Army Engineers, resulted in the enactment by Congress of the Raker Law.

Mr. Grunsky speaks of extraordinary expenditures and lack of study. He neglects to mention that if there were any extraordinary expenditures he was a beneficiary thereof as he received compensation for studies of the Mokelumne River, the McCloud project, and for other services. Possibly Mr. Grunsky's professional pride is hurt because his report on the Mokelumne River was not presented by the City when the case was pending before the Secretary of the Interior. The report was so hastily and disjointedly prepared, and contained such insufficient data that Mr. Freeman and the Army Engineers gave it no consideration. This, together with the fact that Mr. Grunsky's original plans were radically changed, undoubtedly inspires much of his criticism.

Under the provisions of the Raker Act, San Francisco is given the right to store water in the Hetch Hetchy Valley, Lake Eleanor, and Cherry Creek Reservoirs without any restrictions as to the order of development, as well as to construct and maintain power-houses, transmission lines, conduits, pressure tunnels, telephone and telegraph lines, and all appurtenances necessary for the operation of the municipal water-works and power supply. San Francisco must recognize the prior rights of the Modesto and Turlock Irrigation Districts to receive 2 350 sec-ft. when the same can be used beneficially to irrigate their lands and when that quantity of water is flowing in the Tuolumne River, provided said lands shall not exceed 300 000 acres; and San Francisco must further permit 3 000 sec-ft. of the natural daily river flow during the 60-day period immediately following and including April 15th of each year to pass its impounding dams, should this quantity ever be essential to the needs of the Irrigation Districts. Although the Raker Bill limits the irrigation obligations to 300 000 acres, the United States Army Board found that, with proper storage, there was ample for 400 000 000 gal. daily for San Francisco and for 400 000 acres of land.

In the Hetch Hetchy Valley, Lake Eleanor, and Cherry Creek Reservoirs, San Francisco can store economically 689 700 acre-ft. By utilizing other available storage sites within its drainage area, a total of 836 800 acre-ft. can be made available. According to the findings of the Board of Army Engineers* "Four hundred M. G. D. may be supplied San Francisco from the high areas without interfering with Turlock and Modesto rights, with 560 000 acre-feet of storage". The difference between 689 700 and 560 000 is the substan-

* "Hetch Hetchy Valley: Report of Advisory Board of Army Engineers to the Secretary of the Interior, February 19th, 1913," p. 110.

tial excess of 129 700 acre-ft. which San Francisco would have as surplus storage after supplying all needs, by developing Hetch Hetchy, Eleanor, and Cherry. Mr. O'Shaughnessy.

In reservoirs outside the area controlled by San Francisco, the Turlock and Modesto Irrigation Districts can conserve 960 000 acre-ft.; 168 000 from its foot-hill reservoirs and 792 000 from the Upper Tuolumne. According to the report of the Army Engineers, previously referred to:

"The irrigation requirements of the Turlock and Modesto irrigation districts may be provided by their existing rights if conserved by means of 370 000 acre-feet of storage capacity."

From these figures it is evident that in the Tuolumne River drainage area there is ample water to supply the demands of both San Francisco and the Irrigation Districts. Mr. Grunsky's doubts on this subject are no more scientifically justifiable than his assumptions on the invisible leakage from Crystal Springs Reservoir. Even were the danger of a shortage remotely possible, it must be remembered that, before exercising their priority to its limit, the irrigationists are required to develop their own local resources, and that it is expressly stipulated in the Act that the laws of the State of California relating to water shall in any event control as to the priority needs and use of water. By these State laws the City's interests are amply protected. Had no concessions been granted to the Irrigation Districts, San Francisco would not now enjoy a Federal Grant by which it is assured a permanent supply of 400 million gallons of pure mountain water daily. Moreover, as explained by the Army Board to the Committee on Public Lands, should a controversy ever arise between the City and the irrigationists as to their respective rights, domestic consumption, being the highest use to which water can be applied, under the laws of the State of California, the rights of the City will be paramount.

Mr. Grunsky regrets that:

"San Francisco, under the Raker Law, is to expend from $500 000 to $1 000 000 on the proposed storage works in excess of her own requirements, in order to be in a better position to meet the obligation, which she has apparently assumed, to supply some stored water at cost to the irrigation districts.

"San Francisco, [he says] under the same law, will be required to pay for the appropriated water, which should be hers without cost, under State law, at the rate of $15 000 for 10 years beginning in 1919, thereafter $20 000 per year for 10 years, and thereafter $30 000 per year."

Very few will agree with Mr. Grunsky that to make a capital outlay of from $500 000 to $1 000 000 for an increase of water supply from 60 million gallons to 400 million gallons daily is onerous, when

Mr. O'Shaughnessy.

the cost of developing the 60 million gallons daily would be approximately $45 000 000. The money paid by the City to the Government after 1919 is, according to the provisions of the Raker Bill "to be applied to the building and maintenance of roads and trails and other improvements in the Yosemite National Park, and other national parks in the State of California". San Francisco, being the commercial metropolis of California and the clearing house of the Pacific Coast, will naturally profit more by the expenditure of this money than any other city in the State. The prosperity of the Irrigation Districts and the enhancement of the attractiveness of the State's parks, which are visited yearly by thousands of Eastern tourists who make San Francisco their final destination, are of prime importance to the City, and money spent for these purposes will not be wasted. Certainly, it is not to be caviled at, in view of the enormous power concessions granted to San Francisco under the Raker Act.

In Mr. Grunsky's project power was to be developed sufficient merely to pump 60 000 000 gal. daily into San Francisco. The value of the power rights acquired with the enactment of the Raker Bill is conservatively estimated at $45 000 000, on the basis of the findings of the Army Board that 115 000 h.p. could be developed economically. Subsequent studies have disclosed the fact that 200 000 h.p. can be made available from San Francisco's Sierra sources. The percentage of this which will be used by the Irrigation Districts at cost is small. Mr. Grunsky believes that with oil at 75 cents per bbl. power can probably be developed more cheaply by steam in San Francisco than generated by water in the Sierras and transmitted a distance of 150 miles. The refutation of this theory is a matter of record in Case No. 400 before the Railroad Commission of California. In this case, in which the Pacific Gas and Electric Company was under investigation, both hydro-electric and steam plants were studied in order to determine a proper cost for electricity delivered at sub-stations for distribution. There are ten hydro-electric plants, and they include stations with capacities from 660 to 40 000 kw., having a combined capacity of 107 310 kw. There are four steam plants in the Pacific Gas and Electric system, totaling 70 200 kw. in output. Two of these plants have a combined capacity of 63 000 kw. in Curtis turbines. The capital cost of the hydro-electric plants is approximately $136.50 per kw., and the cost of the steam plants is $77.70. The average cost of energy deliverable at sub-stations from hydro-electric plants was $0.00488 per kw-hour. The average energy cost deliverable to transmission lines from steam plants was $0.01248 per kw-hour. These two costs include interest at 8%, depreciation, maintenance, and all operating expenses of generation. The cost of oil at the Oakland and San Francisco plants for the year considered was $0.68½ per bbl. To the cost for hydro-electric current should be added the cost for

transmission and delivery to the sub-station. This amounted to $0.00177 per kw-hour. This brings the cost of hydro-electric current up to $0.00665 per kw-hour. These figures were made in July, 1914, for the purpose of fixing rates for the Town of Antioch. The State Railroad Commission has always resolved the doubt in favor of the corporation, when compiling data for the purpose of fixing rates, and has, no doubt, also allowed the Pacific Gas and Electric Company a considerable sum for capital expenditures made on property which has not as yet been developed to its full capacity. The developments considered in this report are all properties which were constructed primarily for the development of power, and are not plants from which power is merely a by-product, as in the Hetch Hetchy project, where the City must store water for domestic use, and can generate power with a very small additional expenditure. Mr. Grunsky's statement implies that all the electric companies which so recently have expended millions on hydro-electric development in the Sierras, have been guilty of gross misjudgment. If, as Mr. Grunsky states, the power feature is likely to prove a burden, then "the yoke is light and the burden sweet." Mr. O'Shaughnessy.

For an engineer to take issue on a point of law with attorneys and bonding experts of national reputation, who have passed on the validity of the $45 000 000 bond issue to construct the project approximately according to the Freeman plan, seems to be ill advised. It is likewise inconceivable that the people of San Francisco should object to this expenditure, to secure 400 million gallons daily, when they approved the bonds in the expectation of receiving only 60 million gallons daily.

Mr. Grunsky's innuendo, that the City Engineer has "a hand in the game", insinuating that politics is a governing feature in the conduct of the Bureau of Engineering is unjust, as is his statement that the natural results of Mr. Freeman's employment by San Francisco "was that thousands of dollars were needlessly expended". Every unprejudiced citizen of San Francisco, including many of those journalists who decried municipal ownership most energetically and fought hardest against the voting of bonds for the municipal system, agrees that the planning and construction of San Francisco's Municipal Railroads by the present City Engineer were accomplished with good judgment and efficiency. The phenomenal success of this enterprise would have been impossible had the City Engineer, to whom this success is in large measure due, been hampered by politics. The same applies to all of the City's engineering construction that has been undertaken within the past few years.

To prove his contention Mr. Grunsky states:

"Within a year there was named a Board of Consulting Engineers to pass upon the hydro-electric features of the first power installation

Mr. O'Shaughnessy.

under the unauthorized project, understood to be 50 000 h.p. These engineers were designated by name in the City Engineer's request for their appointment. From this circumstance alone it is to be inferred that the political management of the city's water project will be continued."

By what intricate principles of logic Mr. Grunsky derives the conclusion from the premises is not apparent. When it becomes necessary for the chief engineer of a private corporation to request the directors for an appropriation for the temporary employment of one or more consulting engineers, he invariably names the engineers he desires to collaborate with him. Moreover, the personnel of the Board of Consulting Engineers precludes the idea of political preferment. It consisted of F. G. Baum, M. Am. Soc. C. E., retained as consulting engineer on almost every large hydro-electric development on the Pacific Coast and in South America; W. F. Durand, Professor of Mechanical Engineering at Stanford University and Consulting Engineer for Los Angeles power projects; and John D. Galloway, M. Am. Soc. C. E., who has had extensive experience in high-head power plants.

Continuing, Mr. Grunsky discusses the proposed purchase by the City of the properties of the Spring Valley Water Company. He states:

"According to the latest proposition, to be voted on some time next spring, the Water Company will be allowed to retain several thousand acres of valuable land in and adjoining San Francisco, besides some 5 000 acres of land in Livermore Valley. The value of the Pleasanton wells as a part of the system will be reduced because the maximum draft on them is to be limited to 15 000 000 gal. per day, and because the ownership of the 5 000 acres will carry with it the right to draw on the Livermore gravels for all the water that may be needed on these lands * * * there may not be much water left in the gravels for San Francisco."

The City Engineer of San Francisco was directed by the Board of Supervisors, in February, 1913, to designate such lands and properties of the Spring Valley Water Company as he considered it advisable for the City to acquire for use in connection with the early completion of the Hetch Hetchy project. After a very careful and comprehensive study he decided that of the lands owned by the Company at that time, amounting to more than 100 000 acres, it would be advisable for the City to acquire about 68 000 acres. The remaining lands comprised properties which are not desirable for use in connection with either the Spring Valley or the Hetch Hetchy system, some because the development of water from the sources in question would be uneconomical, some because the quality of the water is not satisfactory, and some because the right to divert water to the City would entail the acquisition of expensive riparian rights. In

Mr. O'Shaughnessy.

regard to the 5 000 acres of land in Livermore Valley excluded from the proposed purchase, the City Engineer only consented to the exclusion of these lands with the understanding that the City should have the right to take water from this region to the amount of, but not in excess of, 15 million gallons during any one day, this right being without hindrance or conditions of any sort, the Spring Valley Water Company waiving any and all rights to object to or enjoin the taking of such water, either on the ground that the pumping of underground water to the limit of 15 million gallons daily lowers the subterranean water plane under the lands retained by the Spring Valley Water Company, or that it drains the water beneath the retained lands, or on any other ground whatsoever. As 15 million gallons per day is the ultimate yield to which the Livermore gravels can be economically developed, the restriction of which Mr. Grunsky complains is not an onerous condition.

Mr. Grunsky states that the Hetch Hetchy project has not "yet received the necessary study to determine its main structural features." Enough study has been given the subject to determine definitely that the Grunsky scheme, involving many miles of open ditches, should be abandoned, and active construction has been started on the pressure system.

Mr. Grunsky's complaint of the compensatory features of the Bill was expressed by representatives of hydro-electric power companies in Washington.

There was written into the Hetch Hetchy Bill the conservation principles of the Roosevelt, Taft, and Wilson administrations, and the Federal compensation and regulation are phases of those conservation policies.

These questions were fully debated in the House and Senate, and in the House the vote was more than four to one for the Bill; in the Senate, two to one. Therefore, criticisms of these features are quarrels with the Federal Government policies, which, by the way, the City of San Francisco, so far as the Hetch Hetchy project is concerned, has approved unanimously.

Mr. Hazen.

ALLEN HAZEN,* M. AM. SOC. C. E. (by letter).—The water supply conditions in San Francisco are unique in some respects. Notwithstanding the exhaustive treatment of the author, some of the peculiarities of the situation do not seem to be adequately reflected in his paper. The comparison between San Francisco and Los Angeles is a natural one; it is one that has been made very frequently, and will continue to be made, although there are fundamental differences in the water supply conditions of the two cities.

Los Angeles was situated on a water supply. The primary reason for its existence was that water was readily obtained from the Los

* New York City.

Mr. Hazen.

Angeles River. This excellent supply, carefully developed, has served the population of the Los Angeles district up to the present time, and it is capable of a certain further development. This water is close at hand and at a relatively high elevation, so that it can be, and is, delivered in the city at a very low unit cost. Under these conditions, low water rates have been possible and are natural.

The people of Los Angeles, realizing the limit of the Los Angeles River supply and the effect of that limit on the ultimate growth of the city, went about securing a new supply from the Sierras. The undertaking has been carried out during the last 10 years in a way that commands the admiration of the world. In building these works, the city was extraordinarily fortunate in finding a route for an aqueduct on a continuous down grade from the source in the mountains to the city. Both the source and the intervening land were at sufficient elevations to allow a gravity supply. Indeed, the elevations were more than sufficient, and a large surplus head is available for use in developing electric power. Under these conditions, notwithstanding the long distance, the cost of introducing Sierra water has been surprisingly low.

San Francisco is situated on a harbor. The harbor is a magnificent one, and justifies the location. The site of the city was no doubt selected without regard to water supply, and local sources have proved sufficient for many years, although, as the years have gone by, it has been necessary to go farther and farther afield and to build new works at increasing cost. As time goes on it will be necessary to go still farther, and finally to introduce water from sources entirely outside the district.

A Sierra supply can be brought to San Francisco, but, unlike Los Angeles, an economical aqueduct location from the Sierras is not possible. A mountain range must be crossed, and this lies between two wide valleys but little above sea level. Under these conditions, although the distance is less, the cost of a suitable aqueduct will be increased many fold.

Sources now in use are sufficient to supply San Francisco and the whole surrounding district for some years, although additional storage, aqueducts, and other works are urgently needed to make these sources fully available for present and future needs. By going farther there are many possibilities of additional supply, and ultimately the quantity of water that can be made available, if needed for San Francisco, is enormously greater than the quantity that can be made available for Los Angeles; but the cost to San Francisco of the great supplies of the future will be far greater than that of the supplies which Los Angeles has utilized.

The cost of water in San Francisco and in the San Francisco district will never be as low as it is in Los Angeles. The reason is

found in the great natural difficulties, and in the cost of the works required to gather, transport, and distribute water in the San Francisco district. Mr. Hazen.

The people of San Francisco may regret that they cannot have water at rates that are current in Los Angeles, but they must remember that the higher rates are part of the price that they must pay for their location on their unique harbor. The harbor is worth the price. If water supply instead of harbor facilities had been the dominating influence in locating San Francisco, it would have been built at Sacramento. There water of excellent quality could have been supplied at a price, except for the cost of pumping, as low as water is supplied in Los Angeles or in any city in the country.

J. D. GALLOWAY,* M. AM. SOC. C. E. (by letter).—As a part of his discussion of Mr. Cory's paper, Mr. Grunsky states the following: Mr. Galloway.

"At the time the city thus voted bonds, there should have been created a Board of Water Supply, free from politics. This was not done. The administration at that time and the administrations that have followed, would not let go. The Mayor, who names the Board of Public Works, and who practically selects the City Engineer for the Board of Public Works, the Supervisors, with the Public Service and Finance Committees, the City Attorney, the Board of Public Works, and the City Engineer, all have a hand in the game.

"There is no programme as yet for any change. Within a year there was named a Board of Consulting Engineers to pass upon the hydro-electric features of the first power installation under the unauthorized project, understood to be for 50 000 h.p. These engineers were designated by name in the City Engineer's request for their appointment. From this circumstance alone, it is to be inferred that the political management of the city's water project will be continued. Deplorable as this may seem, it is yet possible that competent management will not be too greatly hampered by political obstruction and political direction; and the hope may be expressed that, despite the unfortunate circumstances of the past, San Francisco may yet achieve an adequate and in every way satisfactory water supply."

As one of the Board of Consulting Engineers on the power development, mentioned by Mr. Grunsky, the writer desires to make the following explanation, in order that the apparent strictures on the Board by Mr. Grunsky may be understood.

The definite plan of a water supply, on which was based the bill granting the right of San Francisco to use the Hetch Hetchy Valley as a storage reservoir, was made by John R. Freeman, M. Am. Soc. C. E., in a very comprehensive report on the entire situation. A clause in the bill required that within a certain definite time the City should file with the proper department at Washington maps showing the definite location of the conduits to be used, so far as they crossed

* San Francisco, Cal.

Mr. Galloway.

Government lands. Mr. Freeman's report was very complete as a whole, but, necessarily, the details, in part, required further consideration. This was particularly so in the case of the development of power as an adjunct of the water supply. Mr. Freeman's suggested design had in view the use of a tunnel for the conduit, leading to a point above one of the proposed power-houses, and thence a steep pressure tunnel in the rock down to the power-house, under a head of about 1 300 ft. As a means of controlling the possible surges in the water conduits, Mr. Freeman had suggested a surge chamber at the junction of the conduit tunnel and the pressure tunnel to the power-house.

It is a well-known fact that though surge chambers of proper dimensions and shape will provide for proper speed regulation of hydro-electric units, they do not in any way provide for taking care of the daily variations in power demand, designated as load factor. The flow of the water in the conduit being practically uniform, the maximum demand on the power-station is limited to the power which can be supplied by the maximum flow of the conduit. If, on the other hand, it is possible to supply at the lower end of the conduit, at a point just above the power-station, a reservoir of sufficient size, the daily fluctuations in power demand can be supplied therefrom, the uniform flow of the conduit passing at all times into the regulating reservoir. It is a rare thing for any power system to have a load factor of much more than 50%, and a number of the important systems of the country have load factors of less than this. In Mr. Freeman's report, the power development was considered as incidental to the water supply. The conduit was considered primarily as one which was to bring water to San Francisco, and the peak load of the power-plant was limited to the maximum capacity of the aqueduct tunnel, more than 19 miles long.

In requesting the Board of Consulting Engineers to serve, Mr. O'Shaughnessy stated that he was confronted with the necessity of presenting maps showing the final location of the conduits, within a limited time; and he also stated that a further study should be made of the power-station design, in order to see if the power development could not be made so as to obtain the maximum development of power, having in view a possible load factor, and without interfering at all with the flow of the water. To answer the various questions asked by the City Engineer really required, on the part of the Board of Consulting Engineers, a complete study of the entire situation of the development of power at the lower plant of Mr. Freeman's design. It is not necessary to dwell on the results of the study as made.

The writer wishes to make clear this point, that the City Engineer was under the necessity of determining these several features before a given definite date. Some appreciation of the problem can be gained when it is said that on a load factor of 50%, the station would

Mr. Galloway.

generate a peak load of about 100 000 kw. The Board of Consulting Engineers could not answer the questions without a complete study of the situation, and the City Engineer was hardly justified in determining the final location of the project until it had been examined.

To one who reads the statements made by Mr. Grunsky, it may appear that politics formed the principal element in the appointment of the Board of Consulting Engineers. In order that the readers of this discussion may form their own opinions, the following information is given: The Board was formed of Professor W. F. Durand, head of the Department of Mechanical Engineering at Stanford University, Mr. F. G. Baum, and the writer, both Members of this Society, in independent practice in San Francisco. Professor Durand, in addition to his duties at the University, has had considerable experience in hydro-electric work. He has made a thorough study of the problems of surge chambers, and was connected with the design of the surge chamber in the power-plant of the Los Angeles Aqueduct. As the surge chamber suggested by Mr. Freeman was an important point in the review, it was felt that Professor Durand's services were especially valuable in this as well as in the other phases of the subject. Mr. Baum has been connected with hydro-electric work in California for nearly twenty years. He was employed on the design of the first long-distance transmission line in the State, with the Standard Electric Company. He was for years the General Superintendent of the Pacific Gas and Electric Corporation, having in charge the building and operation of the numerous plants of that system, which is the largest in California. For a number of years he has acted as the Consulting Engineer of that Company on some of the largest hydro-electric installations in the West. The writer has been connected with the design and construction of hydro-electric works for fifteen years, has acted as Consulting Civil Engineer for the Pacific Gas and Electric Corporation for several years, was a member of the Board of Advisory Engineers on the Sierra and San Francisco Power Company installation, has had charge of the construction of several smaller plants, and recently acted as Consulting Engineer on the installation of the fifth unit, of 10 000 kw. capacity, of the Great Western Power Company. None of the members of the Board is a resident of the City of San Francisco, and all are without connection politically with any one in the city. There would seem to be nothing improper in the fact that the three members of this Board were named by the City Engineer in the ordinance authorizing their employment. Most engineers will agree that it was better for the City Engineer to make the selection than to leave it to the non-technical Supervisors or the Board of Public Works. As a matter of fact, no member of the Board ever conferred with any member of the City Government except the City Engineer. It would also seem that the previous experience of those

Mr. Galloway. named sufficiently justified the judgment of the City Engineer in his selections, and that the appointments were as far removed from the domain of politics as it is possible to have them.

In Mr. Grunsky's statements, the imputation is also conveyed that the various officials of the City refuse to provide for a Board of Water Supply because they all desire to "have a hand in the game". The writer is not acquainted with the opinions of any members of the City Administration, except those of the City Engineer, Mr. O'Shaughnessy, and he has stated publicly, before the Commonwealth Club of San Francisco, and also has expressed the opinion to the writer a number of times, that the proper way to take care of the construction of the Hetch Hetchy project would be to place it entirely in the hands of a Board of Water Supply disconnected from the other departments of the City's organization. Apparently, the whole procedure is at present awaiting the election for the purchase of the local water company's plant. It is quite possible that when this subject is decided, steps may be taken looking to the formation of a Board of Water Supply, but of this the writer has no knowledge. It would seem that some recognition of the public utterances of the City Engineer on this subject should be taken as an evidence of his opinion in the matter.

The writer has been a firm believer in the project of bringing water from the Sierra Nevada Mountains to the Bay districts of San Francisco, which was first definitely set forth by Mr. Grunsky. That the project has suffered various changes since the original plans were proposed, due largely to enlargement of the idea, is only natural. It is believed by the writer that the report by Mr. Freeman was an able and comprehensive document which considered thoroughly all the needs of the situation as it then appeared. Full credit must also be given to Mr. Grunsky and Mr. Manson for their earlier labors along the same line. Mr. Freeman's report was undoubtedly of material effect in securing for the city the rights for which it was struggling. The application for permits under earlier administrations had failed, and it was necessary for the officials in charge to make such compromises as they deemed expedient at the time when the Bill was finally passed by Congress. The conditions became a matter of judgment, and those who were in charge must be given credit for honesty of intentions and a knowledge of the situation as it then existed, even though the conclusion reached may differ from the ideas held by others.

Mr. Baum. F. G. BAUM,* M. AM. SOC. C. E. (by letter).—The writer notes the following statement by C. E. Grunsky, M. Am. Soc. C. E.:

"At the time the city thus voted bonds, there should have been created a Board of Water Supply, free from politics. This was not

* San Francisco, Cal.

done. The administration at that time and the administrations that have followed, would not let go. The Mayor, who names the Board of Public Works, and who practically selects the City Engineer for the Board of Public Works, the Supervisors, with the Public Service and Finance Committees, the City Attorney, the Board of Public Works, and the City Engineer, all have a hand in the game. Mr. Baum.

"There is no programme as yet for any change. Within a year there was named a Board of Consulting Engineers to pass upon the hydro-electric features of the first power installation under the unauthorized project, understood to be for 50 000 h.p. These engineers were designated by name in the City Engineer's request for their appointment. From this circumstance alone, it is to be inferred that the political management of the city's water project will be continued. Deplorable as this may seem, it is yet possible that competent management will not be too greatly hampered by political obstruction and political direction; and the hope may be expressed that, despite the unfortunate circumstances of the past, San Francisco may yet achieve an adequate and in every way satisfactory water supply."

The fact that the City Engineer did select the men, and the further fact that none of them is a politician (and does not even reside in San Francisco) should both be evidence that politics had nothing to do with the appointments. Mr. Grunsky's remark is like stating that two forces acting in the same direction could produce motion in a body in an opposite direction, both his premises being opposed to his conclusion.

The fact that there was immediate necessity for directing certain matters specifically, which had been only dealt with in general by Mr. John R. Freeman, in order to file the proper papers with the U. S. Government, was the reason for the appointments.

Mr. Grunsky's premises, his conclusions, and his inferences are therefore wrong.

E. G. Hopson,* M. Am. Soc. C. E. (by letter).—The discussion of this paper by the City Engineer of San Francisco reveals a point of view of decided interest and importance, being, in fact, the official viewpoint of the situation as it is to-day. Mr. O'Shaughnessy, who is comparatively a newcomer in official circles, undertakes to defend in a somewhat chivalrous manner many of the lapses of his predecessors by endeavoring to reconcile these with the present status and to persuade us that the action now proposed in certain official circles is the best. Mr. Hopson.

Mr. O'Shaughnessy complains that Mr. Cory's paper "consists chiefly of a résumé of matters which were thoroughly and scientifically discussed and settled"; also that "Mr. Cory attempts to revive a number of dead issues, and questions the engineering and financial policies of San Francisco as if these matters had not already been thoroughly

* Portland, Ore.

Mr. Hopson.

considered and disposed of by a number of distinguished engineers", etc. This is the crux of the entire matter, and the writer can well understand that it is at least embarrassing to the official mind to find that, even after all the elaborate investigations that have been made during the past few years and the momentous decisions that have been reached by past officialdom, the main question at issue still refuses to be cavalierly disposed of, but confronts us as if nothing had been done nor any investigations or reports had ever been made.

Thus, after all that has happened, the real issue forces its way to the front in all its baldness and crudity: Does San Francisco want any distant supply? Is the Tuolumne supply what it wants? To these questions may now be well added the minor one as to whether it is not cheaper and better to lose even whatever moneys have been spent on the Tuolumne system to date, than spend forty or sixty good dollars to save one bad one. The last issue has been created by the well-meaning enthusiasts who have led the City to commit itself to expenditures on the Tuolumne supply to an extent amounting, the writer is informed, to more than $1 000 000.

Among the smoke and dust of political and engineering controversy on this classical topic, the following points can be discerned as solid ground, affording certain though limited support. These points are:

(*a*) The practical certainty that the Spring Valley system can be acquired, if the City so desires, at a price that has now been mutually agreed to both by the City and the Company. This is a highly important feature.

(*b*) That the Spring Valley system is susceptible of developing a capacity of between 100 000 000 and 200 000 000 gal. per day, according to the authority that may be preferred. It is important to have in mind that these capacities are, respectively, about double and quadruple the present uses of water in the City.

(*c*) That if the City should acquire the Spring Valley system it would have a municipal supply sufficient to last it for the next 20, or possibly the next 50, years.

(*d*) That the quality of the Spring Valley water is admitted to be excellent.

It may be logically deduced from the foregoing axioms, therefore:

1.—That the objection of the people of San Francisco to a privately owned water supply can be immediately removed by the acquisition of the Spring Valley system;

2.—That there is ample time to consider and settle all the vexed engineering questions as to the available supply in the present system and the City's needs, long before any additional supply to the present sources will be required.

Mr. Hopson.

In the light of the foregoing, does it seem reasonable for the City to proceed at this time to commit itself to any plan leading to expenditures ranging from $37 000 000, as estimated by Mr. Freeman, to $64 000 000, as estimated by Mr. Cory and others, on an independent system that is certainly not needed to-day nor to-morrow, nor for a great many years, and which, moreover, appears to a number of apparently competent engineers and business men to be not well advised?

Mr. Cory and other thinkers of San Francisco urge that the City should pause to consider and weigh carefully the issue and not rush precipitately into these vast expenditures or do anything further to embarrass the community, already heavily encumbered, with another load of debt. They believe there is no reason for action on the Tuolumne or any other additional supply for a long time, and that the City cannot afford to commit itself either to a $37 000 000 or to a $64 000 000 proposition, much less mistake. It is urged, and the writer believes properly, that unnecessary expenditures, which are tantamount to waste, in this direction, must be reflected by curtailments in city improvements along other much more important lines.

Take, for instance, the proposition as it is advanced to-day by the advocates of the Tuolumne scheme—the City is to proceed of its own responsibility to build a metropolitan water supply system intended to serve not only San Francisco but all the bay cities. Did the City of Boston proceed to build the Metropolitan Water System of Massachusetts of its own initiative before the Massachusetts Metropolitan Water District was created, on the expectation that all the other metropolitan cities would enter at some future date and share the cost? Not that the writer is aware. Did the City of New York adopt a Metropolitan Supply sufficient for Brooklyn, Staten Island, and other communities around the mouth of the Hudson before the City was consolidated into Greater New York and all members of the metropolitan district were established as component parts of the system? It did not.

Is there any known case, worthy of being cited as an example, where a metropolitan water system has been built ahead, or independently, of the legal subordination of the several parts of the system to the whole? What would any one think of the business acumen of an individual who, living in a village community, undertook, not only to lay a pipe to supply his own house and barn with water from the near-by spring, but mortgaged his farm to pay for a system of pipes to supply all his neighbors, without taking the trouble to consult them seriously or to make any agreement with them in advance? It does not require much imagination to picture the troubles and embarrassments he would encounter in trying to pay interest on his borrowed money, year after year, or his entreaties to his neighbors

Mr. Hopson.

that they hurry up and take his water and relieve him of the crushing burden he had assumed so rashly on their account. The proponents of precipitate action on the Tuolumne supply matter are endeavoring to place the City of San Francisco in this invidious position.

The question at issue is not wholly one of cost, or the difference between a $37 000 000 Freeman scheme or one of $64 000 000, as estimated by others; nor does it consist of the difference between the estimated capacity of the Spring Valley system, as to whether it can be made to yield 100 000 000 gal., as urged by Mr. O'Shaughnessy, or 200 000 000 gal., as claimed by General Chittenden and others. The real question at issue is whether the Tuolumne proposition is intrinsically a good one, and, even if so, whether it is a good business proposition from the standpoint of the City.

This question, in the writer's judgment, is entirely unsettled, with the preponderance of evidence thus far presented against the Tuolumne scheme. The essential point, however, is that no action should be taken to commit the City to this scheme or any other scheme for at least 5 years, probably not for 10 years, after the Spring Valley system shall have been acquired, and in no event until a Metropolitan District shall have been legally organized.

Mr. Peterson.

O. W. PETERSON,* ASSOC. M. AM. SOC. C. E. (by letter).—The irrigable area of the Sacramento Valley contains from 2 000 000 to 2 500 000 acres, and that of the San Joaquin Valley 4 800 000 acres.† The aggregate mean annual stream flow into the Sacramento Basin is, in round numbers, about 30 000 000 acre-ft., and the inflow into the San Joaquin is about 10 000 000 acre-ft. The northern basin has a run-off equivalent to a depth of 12 ft. over its irrigable area, that of the southern basin being equal to a depth of about 2.1 ft.

It is impossible, however, to conserve the entire run-off. The total capacity of available reservoir sites in the Sacramento Basin is sufficient to furnish a net annual yield of more than 3 000 000 acre-ft. This supply, in addition to the summer stream flow, will irrigate about 1 500 000 acres. The remaining lands can readily obtain a supply from return waters and from wells.

No definite information is available regarding the net yield to be obtained by practicable storage in the San Joaquin Basin. It would be most unusual if a net annual yield of more than one-half of the entire run-off could be conserved in reservoirs and underground storage combined. This would be nearly five times as great a ratio of storage capacity to run-off as that given for the Sacramento Basin. This 5 000 000 acre-ft., in addition to the summer stream flow, would supply about 1 800 000 acres, or somewhat more than one-third of the entire irrigable area in the basin.

---

* La Grange, Cal.

† *Bulletin No. 239*, Office of Experiment Stations, U. S. Dept. of Agriculture.

Mr. Peterson.

The general conditions of water supply in the two valleys are fairly well known. At the recent Inland Waterways Convention, held in San Francisco, Senator James D. Phelan, California's Junior Senator, is reported to have stated the situation most aptly:

"We have before us the great Sacramento Valley—too much water, and the great San Joaquin Valley—too little water. This problem ought to be solved by science."

Now, regardless of this condition of affairs in the two valleys and of its realization locally, San Francisco is proceeding to develop for use outside the basin of the San Joaquin what is probably the best reservoir site in such basin, and to withdraw thereby a supply of water sufficient for the irrigation of nearly 200 000 acres of land. This is more than 10% of the entire area in the San Joaquin Valley which can be fully irrigated. Moreover, a very large proportion of such area is the higher-lying, rolling, foot-hill land adapted to citrus fruits, so that the present value of such a tract of 200 000 acres, with full but undeveloped water supply, is really not less than $30 000 000. The author's figure, $18 924 000, is entirely too low. In time, of course, the value would be much greater.

With this (at least) $30 000 000 added to the estimated cost to San Francisco of the proposed Tuolumne River development, it appears that a fairer basis of comparison with the sources in the Sacramento River Basin would be obtained.

Mr. Rhodin.

CARL J. RHODIN,* M. AM. SOC. C. E. (by letter).—Broadly speaking, Mr. Cory's paper shows that increased water supply for the San Francisco Metropolitan District can be considered from the following sources:

1.—Further development of Spring Valley system;
2.—A supply pumped from the San Joaquin or Sacramento Rivers;
3.—Hetch Hetchy project;
4.—Other Sierra or Mountain sources.

Each of these groups has its peculiar characteristics; they are here briefly summarized.

1.—Spring Valley System.—The storage system and sources of supply of the Spring Valley Company, without doubt, should be incorporated and form an important part of any increased water supply system for San Francisco. As it stands at present, the Spring Valley system can be readily extended to provide much additional water at relatively small cost, and not only can immediate needs be met, but demands for many years can be supplied by the purchase of this property.

* San Francisco, Cal.

Mr. Rhodin.

Due to peculiar conditions in California, however, it is desirable to secure an additional source at this time for use when the economical development of the Spring Valley resources has been reached. This is due to the fact that large quantities of water in the streams of California are continually being appropriated for permanent use in irrigation. When once applied in this way, the water cannot be taken for other purposes without great economic loss to agriculture and the payment of immensely high condemnation prices by the parties desiring the water.

Furthermore, water for domestic purposes should not be taken from a territory where it can economically and readily be put to irrigation use, because the development of California depends so largely on the increased irrigation of its arid lands. Interference with this development by San Francisco indirectly hampers its own growth.

2.—Supply from the San Joaquin or Sacramento Rivers.—Popular opinion in San Francisco, generally, is not favorable to a supply from the lower reaches of the rivers. This feeling may not be warranted by the facts, but it exists, and must be considered. Popular support would be more readily found for a supply of mountain water than for a pump supply however pure it may be. Nevertheless, such a pumped supply, adequate in quantity and quality, does exist.

3.—Hetch Hetchy Project.—Under the Raker Bill, Congress has granted San Francisco the right to develop the Hetch Hetchy project, subject to certain restrictions, the most serious one being that the water requirements of 300 000 acres of irrigation land must first be taken care of. Opinion is somewhat divided as to how much water is required for the irrigation districts. Estimates vary from 600 000 to 1 050 000 acre-ft. per year delivered to the land. The proposed San Francisco supply contemplates 400 000 000 gal. daily, corresponding to about 450 000 acre-ft. per year, making a total demand of from 1 000 000 to 1 500 000 acre-ft. annually. This does not include losses through evaporation, percolation, seepage, and leakage.

The water* discharged by the Tuolumne River, at La Grange, is shown in Table 8, from which it is apparent that, to supply the total requirements, a very complete development of the water-shed will be necessary.

TABLE 8.

Water season.	Total run-off, in acre-feet.	Water season.	Total run-off, in acre-feet.	Water season.	Total run-off, in acre-feet.
1895-96	1 590 000	1900-01	2 720 000	1905-06	3 530 000
1896-97	2 440 000	1901-02	1 610 000	1906-07	3 760 000
1897-98	960 000	1902-03	1 970 000	1907-08	1 070 000
1898-99	1 330 000	1903-04	2 660 000	1908-09	2 650 000

				1910-11	3 410 000

* Water Supply Paper No. 299, U. S. Geological Survey.

Mr. Rhodin.

Under the Act, the burden of providing funds for construction rests on San Francisco, and it is apparent that although that city must carry the project to completion and be responsible for its success and all the contingencies, it has first claim to about the last third of the output only, the first two-thirds going to the irrigation districts.

Under these conditions, even if development costs were low, the nature of the restrictions are undoubtedly serious. As the development costs are far from being relatively low, the advisability of proceeding slowly with the project becomes very important. If it is found that Hetch Hetchy is the best available source for an ultimate large supply, San Francisco must take the risk, but it certainly is advisable to investigate most carefully whether the risks, responsibilities, and expenses attached to Hetch Hetchy cannot be avoided.

4.—Other Sierra or Mountain Sources.—From the view-point that a desirable project should not deprive irrigable areas of future development possibilities, the water-sheds of the San Joaquin River and its tributaries do not seem to warrant further investigations. It is probable that the irrigable area in the San Joaquin Valley can ultimately consume all the economically developed and regulated flow available from these water-sheds.

The Sacramento Valley probably offers better possibilities, the McCloud River, Indian Valley, Yuba River, and other projects have been investigated more or less completely, and, in the main, offer possible solutions; but, some objection attaches to them, as there may be a partial demand on the water for irrigation use. Closer study may well prove some one of these projects acceptable, and free from the objections pertaining to Hetch Hetchy.

Another project, of which comparatively little is known, appears to possess features of considerable merit; this is the Eel River project, briefly mentioned by Mr. Cory. A portion of the drainage area of the Eel River was mentioned in the investigations preceding the passing of the Raker Bill, but did not receive extended consideration on account of insufficiency in size, and lack of cost data. A larger portion of the drainage area of the Eel River could be made tributary, and a much larger supply could be developed.

The Eel River rises in the Coast Range Mountains and flows northwestward through Mendocino and Humboldt Counties, discharging into Humboldt Bay. It passes through a forest country, where the future irrigation demands are not likely to become of importance. Construction offers no abnormally serious problems. From the diversion point, the conduit, in part paralleling the Northwestern Pacific Railway, would permit gravity flow for the greater portion of the distance to Point Pedro on the north shore of San Francisco Bay. The Bay could be crossed at this point by submerged lines to its eastern or Alameda County side. The conduit might then follow the shore

Mr. Rhodin. line to Dumbarton, where the present Spring Valley lines into San Francisco Bay now cross; or a crossing could be made at a more northerly point. The total length of conduit would not differ materially from other proposed projects, and the profile is favorable, with no divides to cross.

Closer investigations may reveal obstacles in the Eel River project, but the general features certainly seem to indicate sufficient merit to warrant a more serious attention than it has received.

Although the problem of an increased water supply to the San Francisco Bay cities has been "on the carpet" for many years, the discussions and investigations which have taken place have been so clouded by political and other extraneous arguments that it is quite possible that a number of meritorious projects have been entirely overlooked.

Mr. Miller. CLEMENT H. MILLER,* ESQ. (by letter).—It is not altogether remarkable, judging from previous policies and reports, that, thus far, the discussion of this important subject has not brought forth the vital facts incorporated in the last official Government report† on the subject, made in response to the Senate resolution of October 31st, 1913, requesting certain information relative to the Tuolumne, Stanislaus, Mokelumne, and Cosumnes Rivers. The following quotations are from that report:

"Capacity of storage available for city water supply.—As shown above in this report, the storage capacity available for use of incorporated cities and towns, after allowance has been made for irrigation, is, for Tuolumne River, 550 000 acre-ft., Stanislaus River, 250 000 acre-ft., Mokelumne River, nothing, Cosumnes River, nothing." (Page 29.)

It should be noted that this allowance is based on the total available storage of 1 050 000 acre-ft., requiring the construction of twenty-three reservoirs, whereas the Freeman report contemplated the construction of three reservoirs with a storage capacity of 685 000 acre-ft., and, on this, estimated a daily available supply of 400 000 000 gal. for San Francisco.

"City water supply made available by storage.—The proper limit of municipal supply which may be made available by means of a fixed storage capacity will be determined by the most severe period for which storage is required. For the rivers under consideration and within the periods of record of discharge of those rivers, the most severe periods have been shown to be in 1897-98 and 1911-13." (Page 29.)

"The following calculation, based on the recent period of deficient run-off of Tuolumne River, indicates that for this period the Tuolumne River is not dependable, with 450 000 acre-ft. of storage for irrigation

* San Francisco, Cal.

† Senate Doc. No. 246, 63d Cong., 1st Sess., November 29th, 1913.

and 550 000 acre-ft. of storage for city water supply, for more than 230 000 000 gal. per day. Calculation follows on pages 30-31." (Page 30.) Mr. Miller.

This conclusion is based on exact data of measured stream run-off as stated during the period of known records, but records of rainfall at Sacramento are available, which show three periods of drought since 1849 more severe than the period of 1911-13, and particularly of that from 1853 to 1861.

The facts relative to quantity of water, available storage, and area of irrigable land contained in this report are not based on any assumption, and cannot be modified to any great extent, but there is good reason to question the accuracy of the assumed "duty of water".

Under the heading "Duty of Water" (page 19), is the statement: "No scientific determination of the probable duty of water in this locality has, so far as known to the Geological Survey, been made." Accordingly, for the purpose of this discussion, the irrigation duty has been assumed at 2.5 acre-ft. of water for the gross acreage of irrigable land, measured at the point of diversion from the stream.

The writer had occasion to question Mr. W. C. Grover, the compiler of the data in said report, as to his knowledge of the subject, and especially called his attention to the report* by Edwin Duryea, Jr., M. Am. Soc. C. E., Chief Engineer of the South San Joaquin Irrigation District. This report shows that, with an irrigating head of 20 sec-ft., the water used per acre per irrigation ranged from 5.8 to 15 in. (without waste), depending on the quality of the soil, a smaller quantity not being sufficient to flood the checks. The duty of water for seasonal irrigation is given as 1 sec-ft. for 80 acres, or 4 acre-ft. per acre, applied on the land from lateral ditches.

Mr. Duryea's report is also based on actual known conditions covering both the Modesto and Turlock Irrigation Districts, and indicates a required duty of water 60% greater than that allowed in the report of the Geological Survey.

As an additional allowance of ½ acre-ft. for irrigation, during the critical period of 1911-13, would have consumed the entire 230 000 000 gal. per day credited as available for the Bay Cities, it is positively certain that a storage capacity of 1 000 000 acre-ft. (if that quantity is ever provided) during recurring periods of drought will only furnish three-fourths of the quantity which will be required ultimately to irrigate the lands tributary to the Tuolumne River.

Mr. Freeman lays great stress on the fact that a municipal water supply must be proven ample beyond any question of a doubt. In view of these facts, clearly proven by the reliable data contained in the reports quoted, the Hetch Hetchy project can in no sense be con-

* *Engineering News*, September 11th, 1913.

Mr. Miller.

sidered a dependable source of supply for San Francisco and the East Bay Cities.

Fortunately, the Report of the Advisory Board of Army Engineers shows conclusively that at least two other sources are available to supply the future needs of the people, even to twice the quantity estimated as that probably required by the need of the present century.

A thorough unbiased investigation of the relative merits of these two sources would probably avoid a repetition of the disastrous blunders and lack of achievement which have been the net results of the efforts of the past twenty years to solve the water question.

Mr. Van Norden.

RUDOLPH W. VAN NORDEN,* M. AM. SOC. C. E. (by letter).—This paper has been commented on, and criticized by, engineers, either with extreme favor, or with disfavor amounting to condemnation. Favorable criticism has emanated from those engineers who are familiar with the San Francisco water-supply problem, but who have not contributed to its solution; also from those who, at some time, have contributed to the study of the problem, but are not now engaged in the development of the Hetch Hetchy scheme to the exclusion of all others. The latter group naturally covers the majority of engineers more or less familiar with this subject. The adverse criticizers comprise only those engineers who are engaged on the development of the Hetch Hetchy plan, and are thus not interested in any consideration or argument which might jeopardize the fulfilment of that project.

Mr. Cory's paper cannot be considered as a cut-and-dried academic technical article of the orthodox variety, which engineers have been taught to expect in the publication of technical societies. From this view-point there is no doubt that the adverse criticism by Mr. O'Shaughnessy is in order; but the time has long since past when papers and their discussions, having as a purpose the accomplishment through engineering science of some great economic improvement, can be limited to mathematical formulas, available data, and deductions from reasonings within narrow limits, where such reasonings are based on premises which are but sage theories, in reality little better than guesses.

Engineering science is becoming recognized more and more as of infinite breadth, rather than infinitely circumscribed by rules and theories. Economic questions, in themselves apparently outside of the radius of action of the civil engineer, questions of law and personal rights, equally foreign to the old-time ideas of the duties of the civil engineer, all enter into the solution of a problem so complicated and so vital to a commonwealth, as is the water supply in question—not as foreign intrusions, but as essential parts of an engineering problem. Civil engineering, in its highest sense, does not, alone, mean the

* San Francisco, Cal.

mere design and construction of dams, tunnels, bridges, or power-plants—given unlimited capital and unlimited time, almost anybody can accomplish such things—but it does mean the selection of ways and means of doing the greatest good for the advancement of mankind with the greatest lasting economies. Mr. Van Norden.

In the San Francisco water-supply work, much deep and thoughtful research has been made. It is not true, as has been often stated, that the people's money spent in this work has been wasted. There has undoubtedly been much time and some money spent in "offside play", and irrelevant actions with political savor, but this has had its value in awakening public interest to action.

The problem, as attacked by Mr. Grunsky, the City Engineer in 1902, was handled, within the limits of cost and time available, in a masterly manner. For the object in view, as it was then understood, Mr. Grunsky's report was a sound beginning; but time has proven that there were lacking, and unknown at that period, the very elements which are shown to exist by the study in Mr. Cory's paper. As economic conditions have become better understood and realized, as the community has developed, and as settlement in the State has increased, much work toward arriving at a basis for obtaining proper results has been done. This has all been creditable, but the problem is a far bigger one than was at first realized, and all this preliminary work has been necessary to obtain insight into the matter.

Finally, the plans which have now been advanced for a proper development of a water-supply system were worked out with the object of coping with the problem in its broadest form. Theoretically, this has been a step in the right direction, but the criticism which has been freely offered is that the gauge adopted has not been broad enough. In order to make the suit fit, the cloth should be selected of ample breadth. In this case, the attempt seems to be to use the cloth at hand and accept a suit which it will make, with the grave possibility that it will not fit, or will be too tight.

The day is past when one engineer can determine the solution of a broad engineering problem by stating that, in the wisdom of his opinion, thus and so are truths, and expect the matter to be settled without further proof. The statement has been made in the criticism of Mr. Cory's paper that the plans for the development of a San Francisco water supply, engineering, economic, industrial, and financial, have been carefully made and settled, and, as an excuse for this statement, a further suggestion is made that this has been decreed by engineers of prominence.

There is ample evidence that a very considerable quantity of creditable and serious preliminary work, as a means toward an end, has been done, but Mr. Cory's paper goes to show that the pure and

Mr. Van Norden.

proper engineering work necessary for the solution of this problem is by no means completed. The paper illuminates the many pitfalls to be encountered, and points to the invisible angles from which views of the problem must be made, without the consideration and treatment of which all previous efforts toward its eventual consummation must be nullified. If this is true, and many engineers believe it to be so, then Mr. Cory's paper is a pure engineering document of the highest order.

Within the last three years, the present civic administration, through the city engineer and the city attorney, has promoted a number of public enlightenment campaigns, or, what might better be termed, a single campaign with intermittent periods of great activity. The noticeable feature of this campaign throughout has been, not to instruct the populace as to its efforts and accomplishments in the preparation for the development of the best plan for a water supply as a broad engineering and economic proposition, but, rather, as to its plans for a reasonable engineering development of the Hetch Hetchy project. The administration has felt itself justified in taking this attitude from the fact that some years ago the City of San Francisco purchased reservoir sites on Cherry Creek and at Lake Eleanor, spending in this purchase considerably more than $1 000 000, and, in 1910 the people voted to bond the city to the amount of $43 428 000, for the construction of the Hetch Hetchy project. Thus this project has been tenaciously upheld as the "best development possible", with little regard to the feasibility of other suggested plans, some one of which might fulfil the conditions to be met in a more satisfactory manner at a less cost to the people.

Much that has been said in this campaign of education has been sound, but there has also been much said with the intent of befogging the issue, and many statements have been made which could not possibly have any basis in fact. The right statements, and those which it would be difficult to substantiate, become apparent on examination to any engineer or investigator, but the many vital points which have been left out and might seriously cloud the appearance of superiority of the Hetch Hetchy source over some other have generally formed grounds for contention, and have resulted in the deadlock that seems to exist at the present time.

What should have been discussions of interest and value have generally been vicious attacks of a personal nature from both sides. Nor in the discussion of this paper have personal aspersions been absent; and these are the things which are not only out of place in a scientific publication, but are inexcusable.

There have been a good many engineers who have become familiar with the situation in a general way, and who would gladly join in discus-

Mr. Van Norden.

sions with the object of arriving at an absolutely true and unbiased basis for the correct solution of the problem. Of these, some are entirely independent and free from any interests touching this water-supply situation, others are more or less interested through clients, and still others are more directly interested; but, unfortunately, all the engineers thus situated, who have not made some expression of their studies or opinions, are divided into two classes. In the first class is the man who does not wish to take issue with the administration, because he feels that he may jeopardize his chance of working into the development in a professional capacity. In the other class is the engineer who does not wish to be accused of being in the employ of some interest whose plans conflict with those as announced by the city engineer.

Throughout this campaign all those who have dared to offer any opinions contrary to those of the administration, or to disagree with, or to take any action which would block the plans of, the administration in its procedure with the Hetch Hetchy project, no matter who they are, or what their standing, have been flatly accused of being in the wrong from some ulterior motive. This accusation has generally taken the form of statements to the effect that such persons were working in the interests of companies, or individuals, with plans for water-supply developments inimical to that of the Hetch Hetchy, and that such persons were receiving pay for their contrary opinions. There was a long period when any engineer daring to express a contrary opinion was said to be in the employ of the Spring Valley Water Company.

Such campaigning has undoubtedly had an immediate desired effect, but, in the long run, it has caused many people to think, and in the end the administration cannot but feel the ill effect of these short-sighted statements, where there has been so little foundation in fact.

In proceeding with the plans for the Hetch Hetchy project, the administration has taken its position—which it has apparently determined not to compromise—on the basis of two engineering reports. These are: the report of John R. Freeman, M. Am. Soc. C. E., which includes several reports on alternative projects by other engineers, and the report made on the order of the Secretary of the Interior by an Advisory Board of Army Engineers. Since the acceptance of these reports, the city engineer has done much work in amplifying and recasting the information embodied, with respect to the Hetch Hetchy project, until his part of the work is probably more valuable than the contents of these two reports combined.

In the earlier work done by the office of the city engineer, namely, during 1902 and 1908, a project was outlined for the immediate development of a supply of 60 000 000 gal. daily, with provision for

Mr. Van Norden.

doubling that quantity. On this basis a system was designed which would compare favorably in cost with that of all other projects, and held no very serious engineering difficulties.

These plans represented sound practice in engineering construction. Furthermore, the water-shed and storage system proposed offered an ample reserve which took cognizance of all complications, and would satisfy adverse claims to water.

The present administration realized the necessity for a water system capable of delivering 400 000 000 gal. per day. This requirement presents a very different engineering and economic problem, compared with which, the first plans are as mere child's play.

With the determination of the necessity of a greater quantity, there was immediately presented an array of possibilities for the development of some other water supply, which, under the smaller draft of the earlier plans would be uneconomical, and hence unfeasible, but, under the new plan of increased output, might prove to be much superior to the Hetch Hetchy project.

These possibilities were apparent to every engineer and investigator who knew anything about the water situation, but, as has been said before, the inflexible stand taken by the administration precluded discussion, or even opinion to any extent.

The Freeman report is, on its face, a justification of the use of the Hetch Hetchy Valley and the Tuolumne water-shed. It is the suit made to fit the cloth. As a mass of statistical information, it is a splendid compilation, and, considering the comparatively meager data on which it was built, is an apparently strong presentation of the subject. The writer has discussed with many other engineers the general engineering plan adopted in the Freeman report, for the purpose of determining the soundness of the reasonings held therein and the plausibility of cost estimates, and to obtain, if possible, suggestions for improving the plan, or lowering the cost. Though there are diverging opinions on these points, the writer believes that the general plan for pressure tunnels, as outlined in the Freeman report, is visionary, and that the estimates of cost are entirely too low. In this opinion he has been upheld by other engineers. The writer does not take the stand that the general plan is untenable, as it is possible to give much latitude in the final designs and determinations, but unless this is possible and unless the foregoing statements are disproved, the entire plan for the development of so great a transportation as 400 000 000 gal. of water per day becomes practically unfeasible in the face of possible supplies from other sources.

The writer is strongly opposed to the construction of unbalanced pressure tunnels. By this expression is meant, a tunnel operating under hydrostatic pressure where the mass of ground over and around

Mr. Van Norden.

the tunnel is depended on to resist the tendency toward bursting, and where there is no hydrostatic pressure from the outside which would tend to balance the pressure from the inside. A balanced and hence proper use of pressure tunnels is illustrated on the Catskill Aqueduct in the crossing under the Hudson River and the tunnel under the City of New York.

In the unbalanced pressure tunnel there is always a tendency toward leakage, depending on the homogeneity of the lining and surrounding structure. This leakage will work toward the surface, and the pressure follows in time. Theoretically, there will come a time when some layer of pressure close to the surface will overcome the resistance of the ground material, and a blow-out or slip will occur, only to be followed by another slip farther back. This action will continue toward the source of pressure until the entire structure of the ground fissures, or gives way bodily.

There have been, to the writer's knowledge, four pressure tunnels in California, all of which have failed in a greater or less degree, and in one manner or another. The two most notable and costly examples of such failures were the inclined unbalanced pressure tunnels in the Sand Canyon Siphon on the line of the Los Angeles Aqueduct. These tunnels were 9 ft. in diameter and were lined with plain concrete having an average thickness of 12 in. They were cut through granite. Both were inclined from the grade of the gravity conduit, these inclines being in the same direction as the respective slopes of the canyon sides, but with steeper inclinations. They were connected at their lower ends by a riveted steel pipe, 9 ft. in diameter, this pipe being run into and concreted in the horizontal portals of the pressure tunnels. The maximum thickness of ground, measured normal to the axis of the tunnels, was about 500 ft. in one case, and more than 100 ft. in the other. Both of these tunnels blew out shortly after they were filled with water. The symptoms were, first, a slight leakage, then a small movement, followed, in one case, by the tearing out of the whole mountain side. It was necessary to replace these tunnels by an all-steel siphon. Aside from the original cost of the work and the cost of rebuilding, the absolute stoppage of flow and use of the aqueduct, had it been in regular service at that time, would have been fully 2 months. The writer cannot conceive of any other result which might have been expected from the use of such conduit construction.

In the plan for the Hetch Hetchy development, there are long stretches of pressure tunnel. In much of this distance, blow-outs or breaks would probably be impossible or unlikely, but there are undoubtedly many places where disasters of this sort might be looked

Mr. Van Norden

for. One such break as was experienced at Sand Canyon would interrupt the flow of water for weeks, or even months.

Between the west side of the San Joaquin and the east rim of the Santa Clara Valleys, there are proposed, according to the Freeman plan, two pressure tunnels with an aggregate length of 30.7 miles. The first of these is to be 27.5 miles long. Geological studies of the country through which these tunnels are to pass show well-defined faults. A break or slip in the ground surrounding one of these pressure tunnels might be the cause of endless disaster to the system; and the emptying and refilling of the conduit, even for inspection or repair, might cause a most serious water famine in San Francisco by the interruption of the supply. Particularly would this be so if the present and proposed reservoirs of the Spring Valley Water Company, which are included as an integral part of the Freeman plan to act as stand-by storage, are not available for use in this connection; and, at the present writing, such an eventuality would seem to be probable, as the purchase of the Spring Valley system by the City of San Francisco has failed to carry at two elections.

The estimates of cost of the Freeman plan were based largely on unit cost data obtained from the work on the Los Angeles Aqueduct, but at a time prior to the actual completion of the work and the commencement of operation of that system. The writer believes that the use of these Los Angeles cost data in the Freeman report was premature and inapplicable to the Hetch Hetchy project; that in many points actual costs would be greater than those assumed; and that the total cost of the work, if it were possible to complete to successful operation in accordance with the Freeman plan, would sum up greatly in excess of the totals given in that report.

To sum up the preceding remarks, the Freeman report is by no means a complete solution of the problem to deliver water from the Tuolumne water-shed, either from an engineering or an economic standpoint, but it serves to disclose the magnitude of the problem of the development of the Hetch Hetchy project and to emphasize the complications unseen by the casual observer, and furthermore, to point out, not the ease with which the project may be constructed, or its cheapness, but rather, the tremendous difficulties of making a source —quite suitable for a small supply of 120 000 000 gal. daily—equal to the duty of the supply and transportation of 400 000 000 gal. daily, even for distant future consideration, which is a figure at the extreme outside limit of the water-shed and storage possibilities, economic conditions not considered, and with little or no factors of safety.

The report of the Advisory Board of Army Engineers is an elaborate and very fair document, considering the variable sources of the data, many of which were of little value, and withal, comparatively meager, on which it was compiled. On a favorable interpretation

of this report for the Hetch Hetchy project, the administration has placed much stress. Mr Van Norden.

The report and subsequent extensions were used with good effect before Congress in assisting the passage of the Raker Bill. Few people have taken the trouble to read this exhaustive report through, much less to study it—an unfortunate condition, because it is broad in its conception, and shows much care and thought in detail.

The criticism of those who are familiar with it is that the administration, in using it, is careful to quote only those paragraphs, sentences, and even clauses, which will react favorably to the Hetch Hetchy plan. To study the report gives one the impression of a broader understanding of the subject by the Board of Army Engineers than the interpretation thereof which has been consistently maintained by the administration.

In placing those data before the Army Board on which to base a report, the city engineer was required to give, not only all data available on the Hetch Hetchy project, but also on the various other projects offered. This latter requirement was a difficult one, because the administration, pledged to the development of the Hetch Hetchy project, possessed only preliminary and incomplete reports already published on some of the alternative projects, and practically no data and little information on the remaining alternatives. It thus became necessary for the city engineer, within a very limited time, to examine these projects, collect data, and make reports of their possibilities, methods of construction, and costs. Attempts on the part of the city engineer were made to proceed with this Herculean task, which would require months where days were available. The results were naturally abortive and of little value, but served to accomplish in a measure the requirement of the administration, namely, to cause the Hetch Hetchy plan to stand in a superior light in comparison with all other suggested plans and projects.

As an example of the frailty of these reports made by the city engineer: two of the alternative projects suggested would be natural flow aqueduct systems, in many ways similar to the Los Angeles Aqueduct. One of these, known as the McCloud project, proposes to take a part of the natural flow from the McCloud River without the requirement of initial storage reservoirs as a primary requisite. The proposed line is to be a gravity-flow aqueduct, partly in canal and partly in tunnels, with the exception of the crossing under Carquinez Strait, which would be a pressure tunnel similar to that of the Catskill Aqueduct under the Hudson River. Throughout its length of about 200 miles, this aqueduct would pass through a very rough and mountainous country—the eastern range of the Coast Range Mountains, bordering the west side of the Sacramento Valley. The greater part

Mr. Van Norden.

of this territory is uninhabited, and the aqueduct location, at the present time, is largely unapproachable by vehicles, because of the absence of roads.

In order to obtain data for the required report on this specific project, the writer was informed that the city engineer sent out a party which made a rapid topographical survey of the reservoir site at the proposed location of the diverting dam in the McCloud River. This required several days. No criticism could be offered for this part of the city engineer's work, except that the work and time spent on this part of the project were rather unnecessary. Another party, so the writer was informed, attempted to cover the 200-mile stretch of the proposed aqueduct line in an automobile, reaching its supposed position by means of an occasional intersecting road, and with the assistance of such portable instruments, including a camera, as would be used in rough reconnaissance work. Three days are said to have been spent in examining this stretch of country to obtain first-hand data for the compilation of the city engineer's report. The strenuosity of this work may be better realized when it is known that, for the greater part of the distance, there are no topographical maps, or accurate maps of any kind, in existence.

The writer is more or less familiar with the country through which this proposed aqueduct is to pass, and fails to conceive how any engineer, no matter how great his ability or experience, could properly cover this line and obtain data of any value whatsoever for a report in ten times the period taken by the party in question, even had he been over the country on some previous occasion. The proof of this contention is found in the reading of the report and the observation of photographs taken, purporting to be points on the aqueduct location, which are, in reality, several miles from its true position. As a further proof that a fair and unbiased presentation of this project was not made, the writer is not unconvinced that a better and cheaper means of bringing the McCloud water to the Bay Cities would be, not by a gravity aqueduct, but by pipe line through the open Sacramento Valley, operating under a static head only sufficient to overcome the friction head of the pipe. This feature was not treated seriously.

The writer is not in a position to state flatly that the McCloud project is superior in the broad engineering sense, that is, good engineering construction at lower comparative cost, better economic conditions, more equable personal rights, and the greatest good to the greatest number, than is the Hetch Hetchy plan properly developed after exhaustive study; but it certainly represents many advantages over points now standing in the way of the Hetch Hetchy project consummation, and is, without doubt, worth very careful and unprejudiced engineering study.

Mr. Van Norden.

The preceding statement is made absolutely without prejudice, as the writer has no interest for or against any plan for a water supply, outside of a desire to see the problem properly solved.

Those features which circumscribe the use of the Tuolumne River for municipal supply, and otherwise impose conditions which enter vitally into the solution of the problem as a whole, that is, the question of economics and personal rights, have been discussed in a limited way in connection with Mr. Cory's paper. The writer believes that there remain ample grounds for further discussion in a broader and fairer-minded manner on both sides, and these points must be all settled before plans for detailed construction can proceed intelligently.

Without going into any of these questions, or making the attempt to supplement Mr. Cory's researches along these lines, there is, however, one point which the writer desires to emphasize:

The City of San Francisco, through its representatives, made a hard fight before Congress for permission to construct reservoirs and conduits to carry water from the Tuolumne water-shed. This fight, which the people of San Francisco as well as the entire country were led to believe was a desperate contest between justice and right, on the part of the people, as against powerful and sinister interests whose only desire was to thwart the Commonwealth of San Francisco for exploitation and personal gain, resulted in the passage of the Raker Bill. This bill was, indeed, a hollow victory, for the adherence to its requirements loads upon the City added responsibilities of great magnitude. It also jeopardizes the water supply by limiting its output in years of low water yield far under the point of maximum use.

Coincident with the promotion of the passage of the Raker Bill, an independent report on the subject of the use of the Tuolumne water by San Francisco was asked for by the Secretary of the Interior, in response to Senate Resolution No. 191, from Dr. George Otis Smith, Chief of the United States Geological Survey. This report, in conjunction with a supplementary report by H. H. Wadsworth, M. Am. Soc. C. E., for the Advisory Board of Army Engineers, in response to the foregoing Senate resolution, is entitled, "Letter From The Secretary Of The Interior Transmitting, In Response To A Senate Resolution Of Oct. 31, 1913, Certain Information Relative To The Tuolumne, Stanislaus, Mokelumne, and Consumnes Rivers In California".

The major premise on which to base any reasoning as to the water available for a municipal supply from the Tuolumne River, based on prior irrigation rights to the water, is the minimum seasonal water allowance necessary to irrigate the lands of the Modesto-Turlock irrigation districts. Several engineers familiar with irrigation requirements in California have placed this allowance at from 4 to 2½ acre-ft. per acre per year, net, that is, measured on the land to be irrigated.

Mr. Van Norden.

The larger figure, 4 acre-ft., was determined by Edwin Duryea, Jr., M. Am. Soc. C. E., from elaborate tests and measurements of water used over both districts, and is an average which he considers must be adopted as a safe minimum.* A figure of 2¾ acre-ft., net, has been given by Burton Smith, M. Am. Soc. C. E., formerly Engineer for the Turlock District, and the lower figure of 2½ acre-ft., net, has been mentioned by Messrs. Grunsky, Cory, and others, and is that adopted by Dr. Smith in his Senate report.

The board of Army Engineers, as shown in Mr. Wadsworth's report, have adopted a smaller water duty for irrigation, allowing 2½ acre-ft. per acre to be irrigated, measured at the point of diversion, and hence allowing nothing for evaporation and seepage in canals and ditches. In this difference lies the variance in the conclusions of Dr. Smith and Mr. Wadsworth. The report of Dr. Smith sums up as follows:

"The following calculation, based on the recent period of deficient run-off of Tuolumne River, indicates that for this period the Tuolumne River is not dependable, with 450 000 acre-ft. of storage for irrigation and 550 000 acre-ft. of storage for city water supply, for more than 230 000 000 gal. per day."

Here follows an elaborate calculation of the actual quantities of storage, in place and as the result of draft by irrigation and by the municipality, beginning with July, 1911, when it is assumed that all storage reservoirs would have been full. An equation quantity, x, is used to denote the monthly draft for city use. Evaporation during the late summer months from the reservoirs devoted to city supply is placed at 25 000 acre-ft. This calculation concludes with the following sentences:

"The condition of storage in the City reservoirs on January 1st, 1914, would be represented by 712 592 — 90 000 (accrued evaporation) — $29x$." "If we assume that the reservoirs are empty on that date, then we have the equation, 712 592 — 90 000 — $29x = 0$." "Then $x = 21\,469$, the amount of water, in acre-feet per month, which the city might have drawn during the period from August 1st, 1911, to January 1st, 1914." "This amount is equivalent to 233,000 000 gal. per day draft over the entire period of 29 months."

There were only 200 copies of this document printed, and most of these were distributed in the Senate, a copy being placed on the desk of every Senator. The fact that very few people have ever seen this report, and that its mention has been consistently avoided by newspapers and by those who have been actively interested in the furtherance of the Hetch Hetchy project to the exclusion of the consideration of all other plans, is interesting.

* "A Study of Irrigation Heads in the Modesto and Turlock Irrigation Districts, California." *Engineering News*, September 11th, 1913, p. 502.

Mr. Van Norden.

Under the present condition of affairs, the writer is of the conviction that the City of San Francisco cannot succeed in developing its future supply of water from the Tuolumne water-shed, or from any other undeveloped water-shed; but with the information and experience now at hand, let the city engineer begin anew, with the broad purpose of exploring every available source and method of supply, equally and fairly, without fear or favor, forgetting for the moment the money already spent and the rights acquired for developing the Hetch Hetchy. A solution satisfactory to the majority can then undoubtedly be found.

Mr. Smith.

BURTON SMITH,* M. AM. SOC. C. E. (by letter).—On page 80 the author assumes that 1 500 000 acre-ft. of storage can be provided, in about forty reservoirs scattered over the Tuolumne water-shed, at a cost of $30 per acre-ft.; and that the entire storage system can be operated with an 80% over-all efficiency. On these assumptions the basic estimates of yield and cost of the Hetch Hetchy project are deduced. Conclusions thus reached are nothing less than dangerous.

The writer, until recently and for a number of years, has been Chief Engineer of the Turlock Irrigation District, and has thus had occasion to examine most carefully and critically all storage possibilities in the entire Tuolumne water-shed—doubtless more exhaustively than any one else has done. Stated briefly, the results of these investigations are that, at most, 1 000 000 acre-ft. of at all practicable storage possibilities exist, and that the average cost of any such quantity would exceed considerably $40 per acre-ft.

These figures generally agree with those of the United States Geological Survey, as given by the Director, Dr. George Otis Smith, in his report on this subject made in accordance with the Senate Resolution of October 31st, 1913.†

On page 83 the author makes some quantity estimates which are based on 1 500 000 acre-ft. of storage—which, as just stated, is far too great—and various irrigation water requirements. Dr. Smith, in the report just mentioned, after stating that the duty of water in that locality is not yet fixed, assumes it at 2½ acre-ft. per annum for the gross acreage measured at the point of diversion from the river. This is undoubtedly lower than (in accordance with terms of the Raker Bill) the Secretary of the Interior of several years hence will determine as the water needs of the land. Fortunately for all parties concerned, it will then be a matter of supreme indifference what the city authorities or the farmers think now or will think then on this point. The only thing of any interest will be the opinion of the Secretary of the Interior of that time, based on experience. Never-

* Oakdale, Cal.

† Senate Doc. No. 246, 63d Cong., 1st Sess., November 29th, 1913.

Mr. Smith. theless, each can now entertain himself by speculating on what that Secretary's decision will be; and the writer's judgment is that, at the very least, it will be 3 and more probably 3½ acre-ft. per acre.

The writer would also be more than deeply interested in a system of operating the storage of such a quantity and character with an efficiency of 80%, or anything near it.

In short, the author's estimates in these particulars are quite too liberal.

Mr. Sloan. C. E. SLOAN,* Esq. (by letter).—Notwithstanding the author's full though concise presentation of this subject, and the interesting discussions which the paper has brought forth, several obvious and important questions are suggested, but are not answered. Some of these have been hinted at in the discussions; others have not.

The title of the paper suggests the first, and perhaps the most important, of these questions, so far as the people of San Francisco are concerned, that is, if this so-called Hetch Hetchy water supply is a water supply for the San Francisco-Oakland Metropolitan District, why is it that San Francisco is acting alone and bearing all the burden?

If it is to be a water supply for the Metropolitan District, why has not that District been formed, and why should not the $45 000 000 in bonds, voted some years ago by San Francisco for a water supply, justly rest on all the Metropolitan District? At none of the many stormy sessions held within the past 10 years, during which Hetch Hetchy has been argued *pro* and *con*, has any real effort been made to establish a Metropolitan District. Why? Principally because the men behind the Hetch Hetchy project are pretty well satisfied that an election to form such a district would be overwhelmingly defeated in the East Bay cities, unless San Francisco would not be able to control the District, in which latter event the Hetch Hetchy project might very well be abandoned.

Then why the proposal for a supply sufficient for all the Bay cities? The Grunsky project in 1902 was for only 60 000 000 gal. daily. The answer is this:

At the time of revoking the "Garfield Permit" by the Secretary of the Interior, the City of San Francisco was instructed, among other things, to investigate all other sources of supply available, and to lay before the Department of the Interior the results of this investigation. An ample supply for San Francisco alone would be 200 000 000 gal. daily, approximately five times the consumption in 1915. From the report of the Board of Army Engineers it will be seen that there are several sources which will furnish such a quantity, and the report clearly points out the fact that the needs of San Francisco

* San Francisco, Cal.

Mr. Sloan.

can be supplied for many years to come without any water from outside sources. Numerous engineers have reported on the resources of the Spring Valley Water Company, and almost all agree with the Army Board that, by developing these sources to their ultimate capacity, San Francisco will not require water from an outside source until 1965. The report of the Board of Army Engineers, excluding half of the possible development of the Peninsula coast streams, places this date at 1947. This being true, it is obvious that a supply for San Francisco proper, from outside sources, of twice 200 000 000 gal., or 400 000 000 gal. daily, is not only a very expensive luxury, but a foolish undertaking for many decades to come.

As stated in the Army Board reports, there are several excellent sources good for 200 000 000 gal. daily. There are only three good for 400 000 000 gal. daily—the Sacramento River, the McCloud River, and the Hetch Hetchy. Nothing simpler: all but these three were at one stroke absolutely eliminated by raising the requirements to 400 000 000 gal. daily. To justify this large demand, only the Metropolitan Water District was needed and suggested—but not formed.

San Francisco is particularly fortunate, compared with the remainder of the prospective Metropolitan District. A careful study of the population curves, water consumption, and immediately available supplies of the Metropolitan District, shows that San Francisco can do without a mountain supply for 50 years, but such is not the case with the East Bay region and Marin County; these must look to some outside source for their water in the very near future. It would seem, therefore, that these communities might well pool their needs and join in a solution of their problems.

The various sources of supply suggested in Mr. Cory's paper are considered with reference to a supply of 400 000 000 gal. daily. Just why he should have set the same minimum quantity as the proponents of the Hetch Hetchy project before Secretary Fisher he does not explain. His careful study of the question is convincing that this quantity of water is unnecessary for the wants of San Francisco for possibly all time to come.

Assuming, however, that 400 000 000 gal. daily is the ultimate demand of the Metropolitan District, the author finds that San Francisco would require only about 100 000 000 gal. daily in, say, 1960, and 200 000 000 gal. daily about 2000 A. D., the remainder being wanted by the rest of the Metropolitan District. If this fact were more generally known, the agitation which has been carried on for the past 10 or 12 years regarding Hetch Hetchy would practically cease, so far as San Francisco is concerned. As no effort has been made by the rest of the District to obtain an outside supply, it should be realized locally that San Francisco is ill-advised in planning to

Mr. Sloan.

bring in a supply of which she can never hope to use more than one-half; for which (on a basis of assessed value) she will be compelled to pay about 70% of the total cost, and very probably all the costs; and the water of which she can only sell to other municipalities, under the terms of the Raker Bill, at actual cost.

However, it does seem that an outside source of water must be obtained for a Metropolitan District (exclusive of San Francisco), and that shortly. Without the financial backing of San Francisco, the Metropolitan District could not assume an obligation of bonds sufficient to obtain water from Hetch Hetchy. From the report of the Board of Army Engineers it will be seen that the quantity of water required for the East Bay region and Marin County is a great deal less than 400 000 000 gal. daily—indeed, about 200 000 000 gal. daily at most—and that this can be had from several different sources at considerably less cost than from Hetch Hetchy. Any of these sources could be financed by the remainder of the Metropolitan District.

Notable among these, as pointed out by Mr. Rhodin in his discussion, is the Eel River supply.* Complete cost estimates on this source are not available; two reports, however, have been made public: one by Messrs. W. R. and N. A. Eckart to the Snow Mountain Water and Power Company, and one by Mr. George S. Nickerson to the President of the Modesto Irrigation District Water Users' Association. Mr. Nickerson's report is on a combination of the Southern Eel River-Putah Creek water-sheds, thereby furnishing a supply of 400 000 000 gal. daily. This would necessitate numerous expensive tunnels and the mixing of the waters of Eel River with those of Clear Lake, which latter waters, as stated in the report of the Board of Army Engineers, is not excellent. The water-shed of the South Fork of the Eel River is in Lake and Mendocino Counties, and almost wholly within the Stony Creek National Forest Reserve.

The territory tributary to Gravelly Valley Reservoir contains 268 sq. miles, and that tributary to Cape Horn Reservoir is 58.5 sq. miles, a total of 326.5 sq. miles. The rainfall in this territory is abundant:

Mean seasonal	43.51 in.
Maximum seasonal	78.62 "
Minimum seasonal	24.99 "

The ratio of maximum to mean rainfall, therefore, is 162%, and of minimum to mean rainfall, 51½ per cent.

The seasonal mean run-off is 26.81 in., and the minimum run-off is 6.90 in. Thus, the ratio of mean run-off to mean rainfall is 55% and of minimum run-off to minimum rainfall is 27.6 per cent.

* See also Report of the Advisory Board of Army Engineers, p. 83.

Mr. Sloan.

The Gravelly Valley Reservoir site is an excellent one. With a dam 150 ft. high, this reservoir would impound 70 000 000 000 gal., or 15.03 in., over the tributary water-shed. This would give an available water supply (during the dryest known period in the past 38 years) of 190 000 000 gal. daily, which could readily be increased to 200 000 000 gal. daily, by taking advantage of the available large storage reservoirs in the East Bay and Marin County regions.

The elevation of the intake of this system would be approximately 1 000 ft. above sea level, and, by following the proximity of the right of way of the Northwestern Pacific Railway Company, a gravity system could be constructed. The hydraulic gradient of this system would permit of the use of light-weight steel pipe or reinforced concrete conduit.

By crossing San Francisco Bay at or near McNear's Point, which crossing offers no great difficulties, the cost of the system would be obviously low. Furthermore, the waters of this water-shed are not now, nor in the future will they ever be, required for irrigation purposes.

The joining of the East Bay regions and Marin County in some such project, and keeping quite apart from San Francisco proper, is perhaps quite as possible as the carrying out of the Hetch Hetchy project along the present proposed lines.

Mr. Duryea.

EDWIN DURYEA, JR.,* M. AM. SOC. C. E. (by letter).—On page 151 Mr. Clement H. Miller states as follows:

"* * *, the irrigation duty has been assumed [by the Geological Survey] at 2.5 acre-ft. of water [per year per acre] for the gross acreage of irrigable land, [the water being] measured at the point of diversion from the stream."

Mr. Miller also states, with reference to the report of the writer as Chief Engineer of the South San Joaquin Irrigation District:

"This report shows that, * * * the water used per acre per irrigation ranged from 5.8 to 15 in. (without waste), depending on the quality of the soil, a smaller quantity not being sufficient to flood the checks. The duty of water for seasonal irrigation is given as 1 sec-ft. for 80 acres, or 4 acre-ft. per acre, applied on the land from lateral ditches.

"Mr. Duryea's report is also based on actual known conditions covering both the Modesto and Turlock Irrigation Districts, and indicates a required duty of water 60% greater than that allowed in the report of the Geological Survey."

Mr. Miller is in error in drawing his conclusion from the so-called Duryea report. The 5.8 to 15 in. per irrigation quoted by him are specific measured instances of actual use; but the depth necessary depends largely on the skill and care with which the land has been prepared

* San Francisco, Cal.

Mr. Duryea.

for irrigation or "checked-up", and on the skill of the irrigator in applying the water; and the depth used too often has no relation to that needed, but, instead, is the maximum which can be obtained, even up to depths harmful to the land.

As stated in the abridgment,* the general conclusions of Mr. P. C. Berkefeldt's report to the writer are as follows:

"For fairly sandy soil and sandy soil, crop alfalfa * * *. For the average run of the land to be irrigated (*i. e.*, the average grade, length, and width of checks, etc.), it is best to use not under a 15-sec-ft. head for a time of about 20 minutes to a half hour per acre; depth of irrigation to be from 4 to 6 in., * * *."

As an average for all the lands in such districts as the Modesto, Turlock, and South San Joaquin, the advisable number of irrigations is believed to be six per year, which, combined with the depth of from 4 to 6 in. per irrigation, stated in the Berkefeldt report to be advisable for alfalfa, is equivalent to a depth per year on the net area irrigated of from 2 to 3 ft., measured on the land. As the result of all the writer's study in connection with the design of the South San Joaquin irrigation system, he decided that the proper average depth for the irrigation of alfalfa is 4.5 in. per month, or 2.25 ft. per year, measured on the net area irrigated.

To provide for a possible "peak use" of the water, and to meet demands for a very ample supply, the Supply Canal and the Main Distributary Canal of the South San Joaquin system were proportioned to deliver 6 in. net water per month on the net area to be irrigated, after all probable losses from absorption and seepage, and without encroachment on the safe "free-board" of the canal banks; and, to provide for "rotation", the Branch Canals were proportioned to deliver the 6 in. each month when in use only about two-thirds of the full time, and the District Ditches when in use only a few days during the month.

The 4.5 in. per month, or 2.25 ft. per year, measured on the net area, are for alfalfa alone. Hardly any other crops require as much water, and in nearly all large irrigated districts a considerable and increasing proportion of the total area is in other crops. Hence, in the writer's opinion, the advisable average use of water in such large irrigation districts should be materially less than 2.25 acre-ft. per year per acre of net area. This is as measured on the lands irrigated that year, presumably about 80% of the gross area of the irrigation district; referred to the gross area, the advisable depth would be materially less than $2.25 \times 0.80 = 1.80$ ft. per year.

Of course, to supply these net depths of water on the lands to be irrigated, enough additional water must be diverted from the river into the headworks of the system to provide for all absorption and

* *Engineering News*, September 11th, 1913, p. 503.

seepage losses from the canals between the river and the irrigated lands. In the design of the South San Joaquin irrigation system, it was concluded that, at the most, 36% of the water diverted from the river might be lost by absorption and seepage from the canals and ditches—that part lost from the Distribution System tending to supply sub-surface irrigation more or less, however, and hence being only a partial loss—and that 64% or more would be available for the direct surface irrigation of the land. Under this supposition, the corresponding depth measured at the diversion point would be (less than 1.80 ft. ÷ more than 0.64) = somewhat less than 2.81 ft. Mr. Duryea.

Although realizing that most irrigators will dissent from this conclusion, it is the writer's judgment that for such irrigation districts as are under discussion (where it is very desirable to keep the ground-water at least 6 ft. below the ground surface and usually difficult to do so on a large proportion of the district), an average irrigation depth of 2.5 ft. per year, referred to the gross area and measured at the diversion from the river, is advisable and not unreasonably low, and is sufficient to furnish adequate irrigation to lands which have been checked with reasonable skill and care, and when irrigated with reasonable skill.

The gross area of the South San Joaquin Irrigation District is 71 050 acres. In the writer's judgment, the necessary and advisable water supply is about 600 cu. ft. per sec., as measured at the diversion point from the river, or about 480 cu. ft. per sec., as measured at the edge of the District lands. Expressed in this way, the corresponding advisable "duties" of the water are about 118 and 148 acres per cu. ft. per sec., respectively.

To permit of building up reservoir storage, even while irrigating, the headworks, the canals, and the tunnels above the reservoir site were proportioned for much greater flows; and to permit of a possible "peak use" of the water and to meet desires for an ample water supply, the canal below the reservoir was proportioned to deliver 650 cu. ft. per sec. at the edge of the District, corresponding to a "duty" of about 110 acres per cu. ft. per sec. The gate outlets from the Branch Canals and District Ditches are proportioned to deliver water on the lands at a duty of 134 acres (gross area) per cu. ft. per sec.

The writer is informed by a skillful irrigator of the South San Joaquin District that (on land prepared with reasonable care by "border" or "strip" checking) he is able to irrigate alfalfa adequately on sandy land with a "head" of 16⅔ cu. ft. per sec., at the rate of 20 min. or somewhat less per acre. That head flowing for 16⅔ min. is equivalent to 4.5 in. of water on the net area.

The writer's remarks apply almost equally well to the discussion by Mr. Rudolph W. Van Norden.

Mr. Wadsworth.

H. H. WADSWORTH,* M. AM. SOC. C. E. (by letter).—This paper and the discussion on it have been read with great interest. On account of his connection with its preparation, the writer has noted with considerable satisfaction the generally expressed commendation of the report of the Advisory Board of Army Engineers to the Secretary of the Interior on the investigations relative to a water supply for San Francisco and the Bay communities.

On the appearance of Mr. Cory's paper, notes were made of several points on which the writer at first had aspirations of basing a discussion. He discovered, however, that with very few exceptions these points bore on the relative development of the Los Angeles and the San Francisco Bay regions; and it seemed wiser to him not to enter this controversy.

In considering the merits of the several distant sources of supply which have been proposed, the author mentions the necessity for caution in using the writer's figures. The writer does not question the propriety of using great caution in this respect, but suggests that a careful reading of his report will show that, as far as practicable, the unit costs applied to the City's Hetch Hetchy project were used in estimating costs of developing other proposed sources; and that successive installations were as nearly equal (in volume) for the different schemes as practicable, so that whether the estimated costs are or are not close approximations; relatively, they are so.

If, owing to the present cheapness of power derived from other sources, the value of hydro-electric power is much less than that used in the report mentioned, the present value of sources of water supply with possibilities of large power development relative to others with no such possibilities may be aggrandized. It can scarcely be doubted, however, that the ultimate (and probably not distant) value of such possible power plants will be substantially that of the capitalization of the market value of the power which they may produce.

As pointed out by Mr. Cory and also by Mr. Van Norden, the actual future need of water from the Tuolumne River for irrigation is uncertain. The writer wishes to call attention, however, to the fact that his estimate of such need is not so materially less than others, as would appear from Mr. Van Norden's discussion.

As stated in his report transmitted to the Secretary of the Interior, and as quoted in the letter of the Director of the United States Geological Survey to the Secretary of the Interior in response to the Senate resolution mentioned by Mr. Van Norden, the writer has taken the duty of water for the Turlock and Modesto Districts at 2½ acre-ft. per acre of land actually irrigated, and has allowed 23% for evaporation and seepage losses. For the total irrigation need from the

* San Francisco, Cal.

Mr. Wadsworth.

Tuolumne River, he applies this duty to an area 60% in excess of the aggregate area of the two districts and gets an annual need of 1 132 000 acre-ft., as against a maximum requirement for any one year of 1 042 043 acre-ft. for the Turlock and Modesto Districts, as reported by Mr. Burton Smith. When volumes of water as large as either of these come to be needed, the time will have arrived for introducing such forms of construction as will decrease waste; and actual losses should be reduced to a figure not very different from the writer's assumption.

The differences pointed out by Mr. Van Norden in results reached by Dr. George Otis Smith, Chief of the Geological Survey, and by the writer, are due to differences in assignment of substantially the same total storage capacity to irrigation and to city water supply use, respectively, and to his (Dr. Smith's) allowing full estimated desirable irrigation use during the extremely dry periods like 1898-99 and 1912-13, at the expense of municipal use, rather than skimping the irrigation use (but not the acquired rights) over an area much in excess of that now in organized districts, or of that now using water for irrigation, so that a full municipal demand of 400 000 000 gal. daily may be supplied through such periods.

Mr. Hammatt.

W. C. HAMMATT,* M. AM. SOC. C. E. (by letter),—The writer is of the opinion that the attacks on the Hetch Hetchy project are a little ill-timed, particularly in view of the discussion by Mr. Van Norden. Bonds have been voted for the fulfillment of the project, part of the necessary land has been acquired, the Government permit has been obtained, a compromise agreement satisfactory to both parties has been entered into between the City and the Irrigation Districts, and ratified by Congress in the form of the Raker Bill. Actual construction has commenced on the road and railroad work, as well as on the diversion tunnel preliminary to the construction of the dam.

At this stage of the proceedings, the only thing which would justify the re-opening of the question is a decided proof of the inadequacy of the water supply, or the impracticability of its utilization. In the absence of such decided proof, the criticism becomes purely destructive, and should be condemned as such. Has any such proof been brought forth? At the present stage, comparisons of the Hetch Hetchy project with the other proposed sources of supply are beside the mark, and only the arguments against the project itself need be considered.

The Freeman report was not solely the work of one engineer, but the collaboration and compilation of many, and no expense was spared to obtain all the possible data necessary to insure the accuracy of the conclusions reached. The subsequent report of the Board of

* San Francisco, Cal.

Mr. Hammatt.

Army Engineers checked this report in its essential points. The only things to be considered, then, are the weight of the contradictions made by other engineers of the conclusions reached from these data.

First, in regard to the cost of the project: Mr. Van Norden has questioned the prices based on the construction cost of the Los Angeles Aqueduct. It is possible, and even probable, that his contentions are correct. It is also possible that changes in conditions of labor and materials between the time when the report was made and the time when the construction will be done will affect these prices still further. This, however, was a matter pertinent to the case of the comparison between the Hetch Hetchy and other available sources of supply, but is not a pertinent matter now that the decision has been made. If the work should cost more than the preliminary estimates (made solely for the purpose of determining the practicability of the project) showed, it will not be the first public work which has cost more than the estimate. Should the additional cost be sufficient to require the raising of additional funds, it will not be the first municipal project which has required an additional bond issue for its completion. The estimates of cost of the other projects submitted are subject to the same reservations.

Second, regarding the feasibility of the pressure tunnel, thrown into doubt by Mr. Van Norden: Apparently, he overlooked the fact that the major portion of the proposed tunnel is pressure in design only. The location of most of the tunnels is such that they carry only sufficient pressure to insure the necessary flow. In the language of the Freeman report (page 121):

"The aqueduct for substantially the entire distance down from the mountains to the edge of the San Joaquin Valley is proposed to be built of the pressure tunnel type, but with barely sufficient pressure to make sure that its section will always be filled under the various conditions of future use."

The exceptions to this are the power-drops, and although these were estimated as tunnels in the Freeman report, there is nothing to hinder their construction in the usual manner, should this be deemed advisable when the final details of the system are worked out. The power-drop tunnels are not essential parts of the project, and the details given in the preliminary report are a small matter on which to base a condemnation of the scheme.

Third, in regard to the sufficiency of the supply: One of the main points on which the opponents of the Hetch Hetchy project base their opposition is the question as to the adequacy of the flow of the Tuolumne River to furnish San Francisco with the necessary supply after deducting the needs of the irrigable lands in its catchment area. In the determination of this matter, the acreage is a known quantity, but the demand of water per acre irrigated is the point on which the

Mr. Hammatt.

determination of the ultimate quantity needed hinges. One reason that the water required for the irrigation of a certain crop is so difficult of determination by comparison with the use on similar lands for which data are available, is that the use in such localities is generally based on the quantity of water available rather than on the actual quantity necessary. There is no doubt that where water is plentiful an excessive use has been made by irrigators, due to their desire to get all they are entitled to, regardless of the effect it may have on their own and near-by land. It is also a fact that much water has been wasted by inefficient methods of application. The data gleaned from systems under these conditions have given rise to much of the doubt as to the adequacy of the 2½ acre-ft. per acre estimated as the ultimate irrigation need of the irrigable land under the flow of the Tuolumne River. There is, however, a constant tendency of irrigation systems, and a consequent constant decrease in the waste of water.

The writer had occasion to make very accurate determinations, as to canal losses and as to the duty of water applied to the land under the San Joaquin and Kings River Canal and Irrigation Company's system, extending over several years. The results of the investigations were as follows:

(1).—That 45% of the water taken into the system was lost by percolation and evaporation in the entire system.

(2).—That the quantity of water measured as flowing to the land for irrigation was 2.44 acre-ft. per acre for 1907, 1.49 acre-ft. for 1908, and 1.44 acre-ft. for 1909.

The drop in the quantity used in 1908 below that used in 1907 was due to the company's change in irrigation charge from an acreage basis to a quantity basis. Prior to 1908, the rate was made per acre irrigated, regardless of the quantity of water used thereon, but, in that year, the rates were changed to so much per second-foot for 24 hours. This change was made for two reasons: First, because the extraordinary demand for water was forcing the system beyond its capacity; and second, because the excessive use was drowning the land. The result of the change was fully up to expectations, as the irrigators, when they were obliged to pay for the water used, reduced their use to their needs. Although the company has since returned to the acreage basis of charges, the educational work has been lasting, and the demand still remains as it was during the years when the rates were fixed on the quantity basis. The duty previously given was for all crops, the prevailing crop, however, being alfalfa, about 70% of the land being irrigated for this crop.

The writer is very familiar with the lands on the east side of the San Joaquin Valley from the Stanislaus River to Kings River, and

Mr. Hammatt. has made several examinations of irrigation systems in this area. From his knowledge of the conditions in this territory, he is able to deduce the following conclusions:

(1).—That the canal losses in the Turlock and Modesto Irrigation Districts would be considerably less than those under the San Joaquin and Kings River Canal and Irrigation Company's canal system, due to the lesser canal length and greater fall of the former. The losses from seepage and evaporation in the canals of the Modesto and Turlock Irrigation Districts would undoubtedly fall below 35% of the total intake.

(2).—That the necessary use of water on the land in these districts would be at least as small as that under the San Joaquin and Kings River Canal and Irrigation Company's system, as the soil evaporation would be less and the sub-surface drainage probably no greater. This conclusion is deduced from an intimate knowledge of the soil conditions in both localities.

The necessary use of water, then, as measured at the intake, would be, considering 1.5 acre-ft. per acre necessary on the land itself, $1.5 \div 0.65 = 2.31$ acre-ft. per acre. Or, if the gross acreage is considered, as about 20% of the land is occupied by roads, buildings, yards, and other non-irrigated tracts, the necessary quantity for the whole area would be 80% of 2.31, or 1.85 acre-ft. per acre. It would seem, therefore, that the allowance of 2.5 acre-ft. per acre referred to in the other discussions would be ample to meet all contingencies of waste due to canal regulation, individual excessive use, and whatever other extraordinary condition might arise. Although there is little question that a slightly greater quantity than this has been used in the past on these lands, it is apparent that the quantity used has been in excess of the needs, as is shown by the rise of groundwater and the drowning of the crops in many localities.

Mr. Griffin. A. GRIFFIN,* ASSOC. M. AM. SOC. C. E. (by letter).—One who has followed the efforts of San Francisco's representatives to secure the Hetch Hetchy water supply for San Francisco, and who has read the papers and talked with the residents of San Francisco, cannot have failed to observe the lack of a grasp of the true situation. This observation applies with almost equal force to the engineer and to the layman, and the silence of the San Francisco press on every subject in the least degree unfavorable to the Hetch Hetchy project is very surprising.

It would seem that, in planning a great municipal water supply, at a cost of $50 000 000, the adequacy of the source should be ample, even to excess, and that the engineering and legal advisers of the project should report adversely unless the source is shown to be ample under the most unfavorable assumptions. Yet we have the peculiar

* Manteca, Cal.

spectacle of the Hetch Hetchy burden being laid on the taxpayers of San Francisco, supported by unsafe assumptions, by half statements of facts, and by absolute silence on all unfavorable features, when it is known, beyond the possibility of a doubt, that the works cannot be supplied to capacity during critical periods which recur with moderate frequency. This is made known even by computations based on assumptions as to storage capacity and irrigation use which are calculated to show the greatest possible quantity available for a municipal supply. Mr. Griffin.

There is actually no definite and conclusive knowledge as to the quantity of water land requires, nor what represents the most efficient use, nor what represents the greatest beneficial use to any person or community, which last is the quantity for which the Modesto and Turlock Districts can rightfully contend. These quantities, in fact, are variable from year to year, depending on the crops, rainfall, prices, and many other factors. The computations which show 400 000 000 gal. daily available for San Francisco are based on an assumption as to the annual use in irrigation, which might easily be 50% greater, and, if it were 20% greater, the quantity shown by the computations would be wholly inadequate, not to mention the fact that, if the assumptions as to the monthly use of water and the quantity of storage available had been more conservative and more in accord with the probable facts, the quantity shown as available for San Francisco would have been decreased still further.

The danger of assuming too small a water requirement for land is illustrated forcibly by the history of the Reclamation Service. The original assumptions led to the making of contracts with settlers to deliver from 1½ to 3 acre-ft. per acre per annum to the land. In many instances it has been found necessary to modify these contracts, if not legally, by common consent; and on some of the projects the United States Reclamation Service is actually delivering 10 and even 20 acre-ft. per acre per annum to some of the lands, and the officials in charge of operation consider these quantities necessary for the best agricultural results. Although extreme conditions are represented by such uses, the general testimony of officials of the Reclamation Service is that it was necessary to revise the first assumptions as to the water requirement of irrigated lands in favor of the use of a greater quantity.

A feature which has been brought forcibly to the writer's attention at various times while engaged in irrigation operations is that the years of deficient run-off are accompanied by deficient winter and spring rainfall in the adjoining irrigated areas; therefore, there is an earlier, a longer, and a greater demand for water for irrigation; that the total quantity used is increased over that used under normal conditions; and that the seasonal distribution of this use is altered.

Mr. Griffin.

It has also been assumed that the Modesto and Turlock Irrigation Districts will develop foot-hill storage to the maximum capacity of the basins tributary to their canals, though, as a matter of fact, it is doubtful whether it will ever be economically feasible to develop them to much more than half this maximum, due to the increasing values of the sites for agricultural purposes and the uncertainty of filling the basins through their two diverting canals.

Aside from the probability of the actual failure of San Francisco to get the desired supply from the Tuolumne, the consequent loss from lack of water, and a partial use, only, of an enormous investment, and the possibility of having to duplicate the investment to secure an additional supply from another source, there should be considered the case of the lands outside the Modesto and Turlock Districts which are dependent on the Tuolumne for a water supply. According to the report on the Irrigation Resources of California, by Mr. Frank Adams,* there are 450 000 acres of valley and plains land tributary to the Tuolumne, and an additional area of foot-hill land between the Stanislaus and the Merced Rivers of 180 000 acres, of which it may be assumed that one-half, or 90 000 acres, is tributary to the Tuolumne, making a total of 540 000 acres tributary to that stream. From personal familiarity with these lands the writer knows that practically all of them are susceptible of being irrigated beneficially; but it is a fact that economic conditions do not warrant the expenditure of the money necessary to provide them with a water supply to-day, and may not warrant this expenditure for years to come. The possibilities of development are there, however, and can never be realized until water is applied to them; and, if the Hetch Hetchy project is carried to a conclusion, most of them can never receive water. This is rendered the more certain on account of the proposed development of so many of the reservoir sites of the Tuolumne for municipal supply. The lands yet to be supplied with water will have inferior water rights, and will be much more dependent on storage than the Modesto and Turlock Districts. The control of 1 acre-ft. of stored water for late irrigation would make possible the use of from 1 to 3 acre-ft. of natural flow for irrigation of the same land in the spring and early summer; but, with the proposed depletion of the total supply of water in the river and the utilization of the best reservoir sites for the San Francisco supply, there would only be left the inferior and expensive reservoir sites and the peaks of the floods for the latter lands, with the probability of no water supply at all in critical periods. This would make any development beyond that at present inaugurated impossible, from an economic standpoint.

* Issued as a State Report in 1912, and also issued by the Department of Agriculture as U. S. *Bulletin 254*.

Mr. Griffin.

The report mentioned previously shows that the San Joaquin Valley has an area of irrigable or agricultural land of more than 8 000 000 acres, with a mean annual run-off of about 11 000 000 acre-ft. and a minimum run-off of about 5 000 000 acre-ft., and that the Sacramento Valley has a similar area of somewhat more than 4 000 000 acres with a mean annual run-off of 26 000 000 acre-ft. and a minimum run-off exceeding 12 000 000 acre-ft., and with a much higher annual precipitation over the agricultural lands. One cannot help being impressed with these figures, and, knowing that water can be taken to San Francisco from the Sacramento Valley at a cost not greatly different from that of the Hetch Hetchy project, with an absolute assurance of its adequacy, one wonders at the persistent partisanship of the people who have led San Francisco into the Hetch Hetchy scheme.

It would seem that, if only for the selfish reason of permitting a tributary community to develop to its highest in order to increase its buying and selling capacity, San Francisco might well keep out of the San Joaquin Valley. Aside from the actual loss that will accrue through arrested development, there is a growing personal antagonism to San Francisco on the part of many people of the San Joaquin Valley, and this has already diverted trade from San Francisco to other centers; and, as time goes on and it is seen more clearly how this enterprise has stifled development, and when, during critical periods, San Francisco shall become involved in altercations and legal controversies with the irrigation interests over the division of water, this feeling will be greatly intensified. Even to-day the Modesto and Turlock Districts, which can be injured very little if the terms of the Raker bill are adhered to, have filed suits against San Francisco, and from time to time are making strategic legal moves for the purpose of checkmating her wherever possible.

Mr. McFarland.

J. Horace McFarland,* Esq. (by letter).—After several years of more or less close connection with the so-called Hetch Hetchy project for the water supply of San Francisco and its appurtenant communities, the writer has a natural interest in this paper.

The position of the American Civic Association, in this matter, is as follows: Those who make up that Association are a unit in the position that no use of water is so important and so beneficial as that for domestic purposes, and at no time in the Hetch Hetchy controversy have they lost sight of this basic fact.

They have felt, however, all the time, that before consenting to the virtual destruction and withdrawal from a possible very beneficent use of a unique and unreplaceable portion of the world's surface, absolute necessity should be shown.

* President, American Civic Association, Harrisburg, Pa.

Mr. McFarland.

Before committees of Congress, before successive Secretaries of the Interior, and, at various times, the writer has contended, first, for the absolute necessity of the best possible domestic water supply for any city; and, second, for that fair and impartial investigation as to various sources of supply which he is constrained to believe, even now, after following the matter for at least six years, has never yet been made in relation to San Francisco.

Having heard voluminous statements by many engineers, and having read countless pages on the subject, he is still of the opinion that the basis of the engineering investigation with respect to the water supply of San Francisco has never been impartial. All the engineers employed by San Francisco and all those called to support their findings have devoted themselves with one voice to exploiting the Hetch Hetchy as the only supply, and to minifying, instead of investigating, other possible sources.

Now, given equal purity and potability, a glass of water from one source is as useful to the residents of any city as a glass of water from another source. Taking into account the turning of the American people toward scenic phenomena and the beginning of a recognition of the magnificent scenery in America to attract visitors, it is, and has been, fair to assume that any great scenic source of water supply ought to be very thoroughly studied, not with reference to its commercial availability for power and then its incidental availability for a domestic supply, but from the standpoint of being used only as a last resource, after all other economically possible sources have been considered.

The writer does not believe this has ever been done, and, as respecting the findings that have been recorded so far in regard to the Hetch Hetchy supply, he is constrained to repeat a remark made in his hearing by a very vigorous ex-President of the United States, referring to a certain Goverment official who was just then terminating a career of actually pernicious activity. He said: "If Mr. B. believes a man to be guilty, he sets out to find evidence to back up his belief. If he doesn't find it, Heaven help the evidence!"

At least three mayors of San Francisco and two succeeding city engineers, together with a dozen other high officials of that enterprising and wonderful city, would testify in the writer's favor that at every hearing where they have met he has reiterated the statement that if the Hetch Hetchy Valley was shown to be the only practicable source of a satisfactory water supply for the City of San Francisco, the American Civic Association would be the very first organization to recommend that it be given up to that city; but San Francisco has never shown this.

The extreme value in promoting and maintaining human efficiency by great recreation places, open to all the people; the great economic

value of unmatched and unique scenery to attract travel and, therefore, revenue to the United States from all the world; a decent respect for the unique glories of our own land, and a regard for the findings and opinions of a man so exalted in his attitude and so high in his knowledge as the late John Muir—all unite in promoting the feeling that the present situation of the Hetch Hetchy matter in its relation to the City of San Francisco is working out to a great wrong to that city, to the United States, and to the whole world. Mr. McFarland.

F. C. HERRMANN,* M. AM. SOC. C. E. (by letter).—The author has taken a very large subject, and, covering it in a broad and general way, has omitted the many interesting engineering features relating to the present water supply system of San Francisco. It is to be regretted that members who have been connected most intimately with the problems of this work and their solutions have not participated in the discussion. Mr. Herrmann.

By reason of climatic and topographic conditions in the region of San Francisco, the problems were unique; and, because that city was isolated from other large centers of engineering activity during its development, their solution was independent in character, often resulting in bold engineering, such as the early use of long lines of thin, riveted wrought-iron pipe of large diameter, high earthen and concrete dams, and ashlar masonry dams of the arch and buttress type with slender cross-section.

Early in the history of these works it was found that long cycles of years having less than average run-off were likely to occur, and, to provide against them, copious storage was essential. The rule was formulated that there should always be available storage capacity equivalent at least to the consumption for 1 000 days.

It is to be hoped that the engineering accomplishments of this system will be presented first-hand to the Profession before very long.

In his discussion, Mr. O'Shaughnessy makes unfavorable comment on the character and reliability of the run-off records of the Spring Valley Water Company, as well as the estimates of water crop by a number of engineers, including the writer. It is to be presumed that he means the Alameda system only, for the records of the peninsular system are probably the best and most reliable anywhere in the western part of the United States.

Water-works engineers of wide experience who have had occasion to examine carefully the hydrographic records of the Spring Valley Water Company have stated that they are very much better than is usual with water-works systems. From his own experience, the writer knows that they are far superior to those existing generally in the West and Middle West.

* San Francisco, Cal.

Mr. Herrmann.

The Alameda system is as yet but slightly developed. There remain to be constructed three reservoirs having an aggregate storage capacity of more than 77 000 000 000 gal., one of which is the Calaveras Reservoir (52 000 000 000 gal.) which is now being built and will be used during the coming season. A number of engineers have made careful estimates of the yield of the Alameda system; others have made statements of yield without careful analysis. The results differ widely, just as they have differed widely in the case of the Tuolumne River. The wide variation in the estimates of yield of the Alameda system is due in some degree to the use of different fundamental elements, such as storage available and allowances for future local consumption.

The waste water of the Alameda system (650 sq. miles above Sunol Dam) finds its way into San Francisco Bay through Alameda Creek. Record has been kept of this by measuring the depth of water over the Niles Dam from 1889 to 1900, and over the Sunol Dam from 1900 to date. In times of high flood both these dams act as submerged weirs, with high velocities of approach. The discharge was computed from these depths by the Spring Valley Water Company by using the formulas, $Q = 4\ 200\ b\ h^{\frac{3}{2}}$ for the Niles Dam, and $Q = 4\ 400\ b\ h^{\frac{3}{2}}$ for the Sunol Dam, which was adopted by Hermann F. A. Schussler, M. Am. Soc. C. E., after numerous observations and measurements. Mr. Schussler has always maintained that discharges computed by these formulas were conservative, particularly in stages of high flow.

Unfortunately, the United States Geological Survey published a record of the flow of Alameda Creek over the Niles Dam, which was fragmentary and based on wholly erroneous data, but indicated that this flow was very materially less than is shown by the records of the Spring Valley Water Company.

This was made quite an issue in the investigations of 1912 by the City of San Francisco preparatory to the hearing before Secretary of the Interior Fisher. Those in charge of the City's affairs appointed a committee composed of C. D. Marx, President, Am. Soc. C. E., of Stanford University, Charles Gilman Hyde, M. Am. Soc. C. E., of the University of California, and C. E. Grunsky, M. Am. Soc. C. E., former City Engineer of San Francisco. The duties of this committee were to make an analysis of the discharge of Alameda Creek over the Niles and Sunol Dams, and of Calaveras Creek at the Calaveras Dam site, from the original records of the Company.

These gentlemen, with the necessary assistants, made a very careful and exhaustive examination of the records, and a survey of the stream bed and structures.

Mr. Herrmann.

The controversy as to the flow of Alameda Creek arose during the period of low-water flow, making it impossible to calibrate the dams by stream measurements prior to the hearing before Secretary Fisher. Messrs. Marx, Hyde, and Grunsky, therefore, made discharge curves for the dams from theoretical analysis.

At the time that these gentlemen began their investigation, Professor J. N. LeConte, of the University of California, conducted a series of experiments for the writer with models of these dams. These models and the approaches to them were exact miniature counterparts of the structures and the stream bed above them as they existed during the times of stream flow observations. Their dimensions were one-twentieth and one-nineteenth of those of Sunol and Niles Dams, respectively. The models were by no means small, having crest lengths of more than 6 ft., and they were calibrated for different rates of flow, from about $\frac{1}{2}$ to 17 sec-ft., and for different degrees of submergence.

Diagrams* were prepared showing the relation of up-stream head to submergence for various values of Q, the discharge curves for the models for different degrees of submergence, the water-surface line at the two dams for the flood of March, 1911, and the arrangement of the experiment station. There was also a diagram of the models.

The flow of water was measured through sharp-edged weirs, using the standard formula, $Q = C \frac{2}{3} \sqrt{2g}\, b\, h^{\frac{3}{2}}$, the coefficient, C, being taken from tables for contracted weirs by the late Hamilton Smith, M. Am. Soc. C. E.

The heads were measured with hook-gauges reading to 0.001 ft., and the degree of submergence was controlled by baffles placed 30 ft. below the models. The conditions were ideal to secure a constant flow for a full set of experiments. The experiments, and the application of their results to the large dams, have been described by Professor LeConte in his report to the writer.

His results were made available to Messrs. Marx, Hyde, and Grunsky before they had finished their analysis. His work, as well as that of Messrs. Marx, Hyde, and Grunsky, was very severely and unjustly criticized by those representing the City of San Francisco at the hearing before Secretary Fisher.

During the winters of 1912-13 and 1913-14 the Sunol Dam was calibrated by careful stream gaugings taken just above it. Independent measurements were taken by the engineers of the City of San Francisco and the engineers of the Spring Valley Water Company; the data taken by both agreed remarkably well up to a gauge height of 8 ft. For gauge heights above that point complete current-

* These diagrams are not reproduced herein, but are filed in the Library of the Society where they may be examined by those who are interested.

Mr. Herrmann.

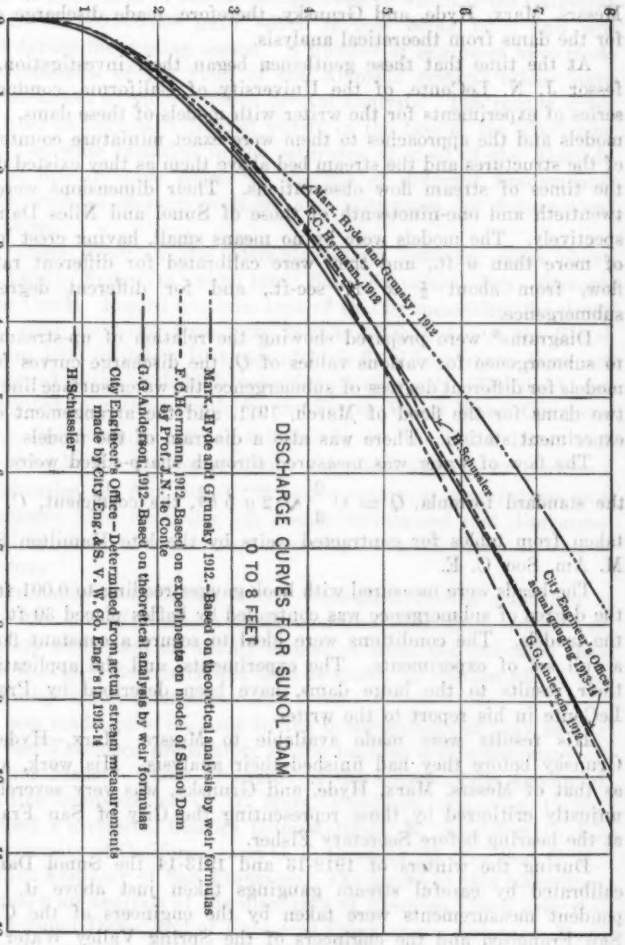

FIG. 28.

meter measurements were impossible because of the high velocity of the water, and satisfactory data were not obtained. However, as the great bulk of the run-off occurs for gauge heights of less than 8 ft., all the current-meter measurements were assembled, and a discharge curve for the Sunol Dam was constructed by the City Engineer of San Francisco. This curve, together with those obtained from the LeConte experiments, the original curve prepared by Mr. Schussler, the Marx, Hyde, and Grunsky computations, and computations by G. G. Anderson, M. Am. Soc. C. E., is shown by Fig. 28. Inspection of these shows the very close agreement between the results obtained by the model of the Sunol Dam and by actual stream measurements. Computation of the total flow of Alameda Creek over Sunol Dam from 1900 to 1913, by the curve from actual gaugings, is about 3% in excess of that obtained by the curve constructed from the LeConte experiments on the model of that dam. Mr. Herrmann.

Much has been written about the use of water for irrigation from the Tuolumne River by the Turlock-Modesto Irrigation Districts, and computations of their future requirements made by different engineers vary between very wide limits. The Modesto Irrigation District feels that it has need for more water than is provided for under the Raker bill, and has brought suit against the City of San Francisco in the California Courts to adjudicate these rights. At the present time it is spending upwards of one-half million dollars to increase the capacity of its main canal, in order that it may divert 2 000 sec-ft. from the Tuolumne River at LaGrange, and is seriously considering the development of large storage at much greater cost, so that it may prolong the irrigation period, and be secure against the critical years of small run-off.

WALTER HENRY BROWN,* M. AM. SOC. C. E. (by letter).—In this paper, as well as in the many discussions brought out by Mr. Cory's treatment of the problem of the water supply of the so-called, but yet unorganized, San Francisco-Oakland Metropolitan District, there is an evident absence of any definite suggestion as to how the Metropolitan District may best secure an enlarged and adequate water supply from any source other than the Hetch Hetchy region. It is clearly the view of many who have participated in the discussions that the Hetch Hetchy project does not offer the economical possibilities desired, yet the contributions are lacking in any enlightening statements as to where the needed water may be obtained—elsewhere than from the Hetch Hetchy source. Other projects have been suggested, in a tentative way, but Mr. Cory has taken occasion to unfold to view what he considers weak points in the Hetch Hetchy scheme, otherwise known as the Freeman Project, but he does not offer a Mr. Brown.

* San Francisco, Cal.

Mr. Brown.

solution for the difficulties—the impossibilities, if you will—he has discovered.

Mr. Cory has always been painstaking in his professional work, and unusually thorough; and it is to be regretted that in this paper, the result of extensive research and experience in and with the local water problem, he should have criticized, severely yet perhaps with justification, the plans proposed in the Freeman Project, without offering a feasible plan for meeting the water requirements of the cities on the Bay of San Francisco.

Mr. Rhodin mentions the feasibility of a filtered supply from the San Joaquin or the Sacramento Rivers, also direct draft from the McCloud River, Indian Valley, and Yuba River, as offering possible solutions. Eel River, in the Coast Range Mountains, to the north of San Francisco, is mentioned as an opportunity possessing considerable merit, but no suggestion of the probable cost is offered.

Mr. Grunsky refers to the Eel River source in the following sentence:

"The water supply problems to the northward of San Francisco Bay are separate and distinct from those of San Francisco and the East Bay cities, and need not be brought under discussion in connection with the larger San Francisco problem."

The question arises in the writer's mind: Why need it not be brought under consideration and discussion in connection with the larger San Francisco problem? If searched for, there might be reasons for the acceptance of the Eel River source not yet brought to the attention of Mr. Grunsky, or of Mr. Cory who has essayed to expand on the Greater San Francisco water problem, criticizing the only source seriously considered, yet neglecting to suggest an alternative.

As a participant in the discussion of this paper, the writer cannot expect, at this date, to go into the engineering and cost details of the Eel River possibilities; but, being familiar with that region for the past seven years, attention is called to the chapter of Mr. Freeman's Report which is devoted to that phase of the situation.

This chapter frankly admits that no study of the Eel River possibilities has been made, and is warrant, in the writer's belief, for some earnest effort being made toward determining the value of the Eel River region as a source of supply for municipal needs. In the first place, it is not necessary, or even desirable, to make the bay crossing under the Golden Gate in the presence of the more favorable crossing offered at McNear Point, near the City of Richmond. San Francisco is not, of necessity, the only objective point in the proposed Metropolitan Water District. Oakland, Alameda, Berkeley, Piedmont, Richmond, and many other thriving cities are expected to contribute toward the construction costs of a new and great water

supply, and their interests should be considered in the selection of, as well as in the payments for, a new supply; and, for these combined communities, the Golden Gate route has no part in the problem, under any form of development of the Eel River sources as yet in evidence. Mr. Brown.

Cost of Initial Development of Eel River Sources.—Construction estimates have been made for an initial development of the Eel River supply for from 12 000 000 to 15 000 000 gal. daily. Peculiar as it may seem, it would not be profitable to bring into the limits of the proposed Municipal Water District, at this time, more than 15 000 000 gal. daily, at the outside. The writer was very much surprised when this state of affairs was developed through the analysis of evidence given at a recent hearing before the California Railroad Commission in connection with the East Bay water situation. The reason there is not, at this time, justification for bringing in more than 15 000 000 gal. daily is that the Calaveras Dam is well along under construction, and will provide for all needs of San Francisco proper for the generation now interested in these affairs. The present consumption of the East Bay Cities is somewhat less than 18 000 000 gal. daily, and, with the existing local resources, there is not room for the disposal of more than 15 000 000 gal. daily, which might be secured from a distant source.

Of course, the cost of water per 1 000 gal. to the consumer diminishes with an increased capacity of the supply system, but even so small a quantity as indicated can be delivered into the local storage of the East Bay Cities, at an elevation of 200 ft. above sea level, for less than $5 000 000, gross construction expense, with attending gross operating and overhead charges of less than $1 500 per day. These figures cover the cost of building a pipe line from Eel River, with a capacity of 20 000 000 gal. daily, and would enable the delivery of water to the Bay District for a rate of less than 15 cents per 1 000 gal. The Eel River sources, without storage at points of diversion, by conduit route 130 miles from San Francisco, and utilizing less than the existing terminal storage facilities, will, without question, supply 12 000 000 gal. daily, and, with the storage facilities available at the head-works, at Gravelly Valley, 180 000 000 gal. daily may be depended on as the ultimate safe yield from that particular unit of the Eel River development. When more than 180 000 000 gal. daily are required for the Metropolitan District, there is more water available in the Middle Fork of Eel River, 38 miles north of the South Fork, where an additional supply of 350 000 000 gal. daily may be obtained. This gives a total of 530 000 000 gal. daily from Eel River.

The writer has made extensive studies of the Eel River regions, in connection with work other than the Greater San Francisco water problem, and offers to his associates in the Profession, who are in-

Mr. Brown. terested in this particular problem, the following notes, subject to further expansion should interest warrant:

1.—The combined Eel River sources are suitable for a programme of gradual and economical development without throwing excessive or undue burdens on any one generation of the communities' inhabitants.

2.—The Eel River sources as here proposed have never, at any time, been investigated by the City authorities, or by the Advisory Board of Army Engineers, as a source of municipal water supply.

3.—By taking a municipal water supply from the Eel River sources, no community interest can, in any way, be threatened or jeopardized by being deprived of water. Litigation, such as threatened in the San Joaquin Valley over established and valuable water rights in connection with the proposed Hetch Hetchy diversion to San Francisco, would thus be obviated.

4.—Irrigable lands in the valley of the Russian River, now without irrigation, could be supplied with excess water from the Eel River sources, following the example or policy of Los Angeles in building up and making more productive its adjoining areas.

5.—To leave to the San Joaquin Valley the water available to it, even though the farmer's ideas of his needs may appear extravagant to the man in city life, will result in that community's growth in population and commerce, and actual thrift, which will naturally center in and build up the cities on the Bay of San Francisco.

6.—The region of the Eel River water-shed, above points of diversion, is in its virgin state. Its mountain ranges run from 6 000 to 8 000 ft. above sea. The water therefrom runs free of pollution by habitations; the maximum hardness at periods of lowest water is 17°, French scale; there are no lumber camps or summer resorts on its areas; and the entire water-sheds of both branches of Eel River are enveloped by the Stony Creek National Forest.

7.—Precipitation on large portions of the Eel River region occurs at the rate of 100 in. and more per annum. There are no requirements for irrigation, and all the water in question runs to waste to the sea.

8.—The combination of sources from the Middle Fork of Eel River and the South Fork of the same stream makes a feasible, practicable, commercial project that should receive, at least, the attention of those seriously concerned in the San Francisco-Oakland Municipal Water District problems.

Mr. Cory. H. T. Cory,* M. Am. Soc. C. E. (by letter).—The writer's purpose in preparing the paper was, first, to acquaint the members of the Society with the general local water situation, and second, to present the subject for discussion by technically trained men before a technically trained audience.

* San Francisco, Cal.

Mr. Cory.

The writer, therefore, is not only much gratified with the interest shown by the volume of the resulting discussion, but also that those who have participated include the present City Engineer of San Francisco; the ex-City Engineer who originally suggested the Hetch Hetchy source of supply and outlined the first Tuolumne project; two of the three engineers who have been called into consultation with respect to power features of the present Hetch Hetchy project, and four others who have been employed by the City during the preparation of the Freeman Report and the water-rate cases now pending on the San Francisco side of the Bay; the engineer in charge of preparing the Army Board Report; a member of the Commission which reported to Secretary Ballinger in 1910 on the need of the Hetch Hetchy Valley; the Chief Engineers of the Modesto, the Oakdale, and the South San Joaquin Irrigation Districts; and the President of the American Civic Association.

Analysis of the various comments shows that no one has criticized the writer's conclusions regarding the following:

1.—The future population curves of the San Francisco-Oakland Metropolitan District as a whole and of the several individual sections thereof;
2.—The future water requirement curves of the district and of the several different sections comprising it;
3.—The relative bonded debt, municipal construction needs, and amount of taxable property in San Francisco and Los Angeles now and in the future;
4.—The fact that the problem of a distant water supply is far more real to the East Bay Cities than to San Francisco;
5.—The fact that the East Bay Cities, particularly, should endeavor to get water costing the consumer little if anything in excess of 15 cents per 1 000 gal., and regard such cost limit as of prime importance;
6.—The essential factors affecting the selection of a distant water supply source;
7.—The advantages and disadvantages of various distant water supply possibilities—with the exception of the Hetch Hetchy and Eel River;
8.—The fact that the Sacramento Valley has an excess of water and could easily spare all of San Francisco's needs both present and future; and that the San Joaquin Valley has a deficiency of water for its own needs, no matter to what extent conserved;
9.—The desirability of a water board to handle all water supply problems, which board should be entirely separate and distinct from any and all other municipal authorities.

Mr. Cory.

It is realized, of course, that lack of criticism does not necessarily imply universal approval.

With the single exception of the present City Engineer, Mr. O'Shaughnessy, there have been no expressions of approval concerning the wisdom of San Francisco in building the Hetch Hetchy project, as determined by the provisions of the Raker Bill. Mr. Galloway, states that he is, and has been since the Grunsky proposal of the Tuolumne source in 1902, an advocate of Sierra water, and Mr. Hammatt feels that the City has gone so far in the matter that discussions of the Hetch Hetchy project are out of place. All other comments which touch on this phase of the subject are either condemnatory or doubtful.

The City Engineer alone takes issue with the statements made concerning the yield of the present water sources when fully developed.

Considerable diversity of opinion was expressed concerning the water needs of 300 000 acres of land in the Turlock and Modesto Irrigation Districts.

The discussion has been so voluminous that it is impracticable to summarize the views of those taking part, or, generally speaking, even comment on the various points brought out. As a matter of fact, there is no reason to do so, for, by a careful reading of all the discussions, one can very easily decide the proper weight to be given the various expressions of opinion.

An exception is the discussion by Mr. O'Shaughnessy, which requires some comment. He points out that the writer was in error in stating that San Francisco had more than 2 200 saloons, and that the official figures are 2 051. The writer is glad to be corrected, and will only say in explanation that the figure used, which was taken from the Assessor's records, through misinterpretation of the data, included more than 200 one-day licenses. Neither of these figures quite tells the story, because of the "corner grocery", as the U. S. Revenue Retailers licenses issued during the quarter ending June 30th, 1914, were 5 818, or about 1 in 85 of population.

He also notes that the population curves in Fig. 2 are not identical with those given out by the Census Bureau for the respective metropolitan districts. In the paper the writer was careful to state that "Greater San Francisco-Oakland" and "Greater Los Angeles", as used throughout the paper, comprise, respectively, all the territory which should logically join in a common water supply within circles of 30 miles radius. The populations in these districts are naturally not identical with those found by the Census Bureau for districts with different boundaries, although, as a matter of fact, the differences are quite small.

He also corrects the writer's figure, "about 100 miles of steel pipe", in the Freeman-Hetch Hetchy project, and states that there are 87

miles. The writer was under the impression that more than 13 miles of the pipe line was a double line, but is glad to be put aright. Mr. Cory.

Regarding the planning and construction of the Municipal Street Railway system and other City work by Mr. O'Shaughnessy, the writer is very glad of this opportunity to express his unqualified admiration therefor. All of such work has been planned along broad lines, of high character, aggressively prosecuted, and carried through without the slightest hint of favoritism or political meddling.

In spite of the writer's statement relative to Table 1, showing the estimated yield of various Spring Valley water sources, Mr. O'Shaughnessy comments as though the paper had not emphasized sufficiently the differences of opinion of the various engineers who have investigated the matter. Mr. O'Shaughnessy has stated:

"For years there has been much investigation as to both the ultimate and the available yield of the Spring Valley sources. Many reports and estimates have been filed by various parties—some representing San Francisco or the East Bay Cities, or both; others working in the interests of one or more of the water companies supplying those cities. In matters of this sort it usually happens that investigators of the latter class are very optimistic in their estimates, and those of the former class are more conservative."

A very important method of examining and comparing safe water yields with given storage capacities has been presented in a paper* by Allen Hazen, M. Am. Soc. C. E. In that paper, Figs. 40 and 41 give the curves for California conditions for 95% and 98% dry years, respectively. Throughout much of California the evaporation is in excess of the rainfall, and in the southern part of the State, particularly, the extent of over-year storage required is extraordinarily large on account of the run-off conditions shown in Fig. 17. From the safe yield, read off from Mr. Hazen's Figs. 40 and 41, excess of evaporation losses must be deducted—treated as a part of the draft. The correction ranges from nothing in the Sierras and Upper Coast Ranges to 5% in the Bay region and 25%† in the vicinity of San Diego.

Mr. Hazen's method makes very simple the estimation of safe yield throughout the various parts of the State, and is on the same basis with respect to severity of the drought conditions provided against. That is to say, years are considered as types—no one actual year being taken—and are designated or defined, so far as degree of dryness is concerned, by their position in order of dryness. For example, a year of such a degree of dryness that 95% of the years are wetter—have larger quantities of run-off—and 5% are dryer, is called a 95% dry year; similarly, a year of which it is true that 98% of the years are wetter and 2% are dryer, is called a 98% dry year.

* *Transactions*, Vol. LXXVII (1914), pp. 1539 to 1669.

† Based on 52 in. mean annual evaporation from water surfaces. The California Railroad Commission uses a larger figure.

Mr. Cory.

Thus, a 95% dry year standard means that there will be a water shortage in 1 year in 20, and, with a 98% dry year standard, shortage will occur only in 1 year in 50. Table 9 shows the length of the run-off record, mean run-off, in acre-feet, coefficient of variation, and available storage, in acre-feet, of several streams, including the important ones mentioned in the paper and in the discussions. These data were used in connection with Mr. Hazen's Figs. 40 and 41, the corrections for excess of evaporation have been applied, and the resulting net yield is given in Table 10 under the headings "95% dry year" and "98% dry year".

In 1907, Mr. O'Shaughnessy became Chief Engineer of the Southern California Mountain Water Company, supplying water to the City of San Diego. On June 5th, 1912, the City bought the property, and the bond election was held on August 15th, 1912. The vote was 6 948 to 1 405, due to assurances from the company that the plant output was a "sufficient supply of water to take care of the increased population and growth which the Panama Canal and other factors are bound to create."* The mean daily consumption in 1912 was 5 819 214 gal., and in 1913, 6 850 000 gal., the city's growth being rapid.

The system then included the Otay and Morena supplies, which were then held by Mr. O'Shaughnessy as being good for 13 500 000 gal. daily. In April, 1914, at a hearing before the California Railroad Commission in connection with related matters, Mr. O'Shaughnessy testified that he had in the past year and a half reduced his estimate of the safe yield from Morena Reservoir to 6 500 000 gal. daily, the safe yield from Otay remaining at 400 miners' inches, equivalent to 5 160 000 gal. daily. He also testified that in 1912 he had considered Cottonwood Creek, fully developed, to be good for 1 500 miners' inches (however, presumably with 46 000 acre-ft. of storage at the Barrett Dam), but now estimated that with the creation of 27 675 acre-ft. of storage at the Barrett Dam site, and the 46 000 acre-ft. of storage existing at Morena, the safe yield would be 15 000 000 gal. daily; and that the present safe yield could be increased by 5 000 000 gal. daily by creating 27 675 acre-ft. of storage at Barrett.† The Engineering Department of the Railroad Commission at the same hearing determined the safe yield of the Otay as 2 500 000 gal. daily; of the Morena, 3 500 000 gal. daily; from the Cottonwood, complete development, 5 400 000 gal. daily; and the increase in safe yield by the construction of the Barrett Reservoir, 1 900 000 gal. daily.

Within less than a year, San Diego realized that the water supply must be increased, and Mr. O'Shaughnessy and J. B. Lippincott, M. Am. Soc. C. E., were called in to report on additional proposed sources

Mr. Cory. of supply, including the San Luis Rey River at what is known as the Warner Dam site. Mr. O'Shaughnessy, at the same hearing before the Railroad Commission, estimated the safe yield from this source at 13 000 000 gal. daily.*

Table 10 should be considered in connection with Mr. O'Shaughnessy's criticisms of the writer's presentation of the safe yield from local sources based on investigations by several local engineers and Brig.-Gen. H. M. Chittenden (*Retired*), and A. O. Powell, of Seattle; William Mulholland and J. B. Lippincott, of Los Angeles; George G. Anderson, of Denver; Allen Hazen, of New York City; and Leonard Metcalf, of Boston, all Members, Am. Soc. C. E.; the Army Board, and, respecting the sources available for the East Bay cities, accords with his own conclusions.

It is interesting to note in Table 10 that if the available storage in the Tuolumne water-shed is 1 000 000 acre-ft., as estimated by the United States Geological Survey, the safe net yield (95% dry year standard) is only 1 066 000 acre-ft. Using the maximum storage in the basin, as taken by the writer, 1 500 000 acre-ft., the safe net yield is 1 275 000 acre-ft. This storage Mr. Burton Smith considers entirely too high, without exceeding a reasonable cost per unit capacity. Should it be possible to create 1 800 000 acre-ft. of storage in twenty-six reservoirs, as Mr. O'Shaughnessy proposes, the net safe yield would be 1 380 000 acre-ft. The writer, however, knows of no one except Mr. O'Shaughnessy who has ever suggested the possibility of developing such a tremendous quantity of storage.

Mr. O'Shaughnessy quotes from a report by Mr. John R. Freeman, dated March 21st, 1914, to the City Attorney and the City Engineer of San Francisco on "Reservoirs Ultimately Required for the Hetch Hetchy Water Supply of 400 Million Gallons Daily for San Francisco under the Terms of the Raker Bill." The writer has several times had occasion to review hydrographic estimates of Mr. Freeman, and has always arrived at results essentially similar to his. Accordingly, thinking the excerpt given was probably conditioned on assumptions as to irrigation needs, etc., permission to examine the report was asked. He was advised by the City Engineer that the report was not a public document, and permission to see it was refused. Comment on the report or the quotation from it, therefore, is impossible.

The writer is very much surprised that Mr. O'Shaughnessy should express inability to understand the writer's statement that the City had revised the estimated cost of the first 160 000 000 gal. daily installation from Mr. Freeman's figures of $37 501 400 to $64 000 000. The conference between the representatives of the Turlock and Modesto Irrigation Districts and the City Engineer and City Attorney of San Francisco, held in Washington while the Raker Bill was being

* *Ibid*, p. 675.

framed, resulted in several drafts of the bill. One printed on June 23d, 1913, provided that the irrigation districts, before demanding any stored water, should, whenever the Director of the United States Reclamation Service might require, provide additional storage at an initial cost not to exceed $15 per acre-foot of storage capacity. In the bill as passed all provisions requiring the irrigation districts to do anything positive were eliminated, by the House Committee on Public Lands, for legal reasons. However, in discussing this June 23d, 1913, draft of the Raker Bill, it was asked that such limiting cost per acre-foot of storage be raised from $15 to $20. The irrigation districts' representatives declined, pointing out that, according to the Freeman estimate, the construction of the Hetch Hetchy Dam to its initial proposed height would create storage costing only $12.50 per acre-foot, and when continued up to the final height of 300 ft. (capacity then 330 000 acre-ft.), would reduce the cost to $8.50 per acre-foot. The City Engineer denied this, and stated that his revised estimates of the Hetch Hetchy Dam showed the cost to be in excess of $20 per acre-foot, and, further, that his estimate for the entire Freeman first installation was also much greater, and in fact was $64 000 000. These statements were official utterances of the City Engineer at official conferences with official representatives of the irrigation districts. Recently, on being reminded of this by the writer, Mr. O'Shaughnessy answered by saying that the too low unit prices of Mr. Freeman were just about offset by reductions resulting from no irrigation waters being permitted to be brought to the Bay region. However, on page 123 he says: Mr. Cory.

"Thus far, no radical departure from the Freeman plans is proposed, except that it may be considered advisable to install initially a smaller pipe line, 45 miles long, across the San Joaquin Valley for a supply of 60 000 000 gal. per day, and to develop at once 50 000 hydro-electric horse-power."

The differences in cost between 45 miles of pipe with respective capacities of 60 000 000 and 160 000 000 gal. daily, can hardly equal the increase of the City Engineer's estimate of $64 000 000 over the Freeman estimate of $37 501 400.

The writer, the Army Board, and Mr. O'Shaughnessy are in entire agreement as to the very great desirability for San Francisco Bay Cities to determine soon what distant water supply source or sources will ultimately be wanted, and immediately arrange for the necessary water rights. Special legislation, granting to the Bay region the water rights desired and protecting these rights indefinitely until it may be found desirable to develop the sources, can be obtained almost for the asking from any session of the State Legislature. Even if a Constitutional amendment should be necessary, very little more effort would be required, as the sentiment throughout the State is certainly

Mr. Cory.

almost unanimous in favor of assisting important communities to plan intelligently in broad, far-seeing ways for their water needs especially.

Quotations of the cost of developing electrical energy in the hydro-electric and the steam plants, respectively, of the Pacific Gas and Electric System, as set forth in Application No. 400 before the California Railroad Commission, are made as a "refutation of this theory" as to the value of hydro-electric power in the Hetch Hetchy project as expressed by Mr. Grunsky and the writer. The Pacific Gas and Electric Company's load factor is about 62%; the hydro-electric plants are naturally run all the time possible, and have a much higher load factor, and the steam plants a much lower load factor. Hence the load factor of the combined hydro-electric plants is more than three times that of the combined steam plants. It is almost an axiom that, with any given set of conditions, the relative economy of hydro-electric and steam plants is determined by the load factor. As a matter of fact, the writer's comments in the paper concerning the value of hydro-electric power are believed to be entirely fair, candid, and correct.

In several places Mr. O'Shaughnessy, both definitely and by inference, states that the Raker Bill contains provisions requiring the irrigation districts to develop water storage of their own. As already explained, in the original negotiations between the representatives of San Francisco and the irrigation districts, a plan was worked out whereby the irrigation districts were to provide storage as should be required by the Director of the Reclamation Service. The House Committee on Lands, however, decided that Congress, in framing the bill, had power to impose conditions of performance only upon the grantee. Accordingly, all of such provisions were eliminated, and the legislation, as passed by Congress, and the provisions thereof officially accepted by the City of San Francisco, contain no reference or implication requiring the irrigation districts to provide any additional storage.

The following quotations should be read in connection with Section 9 of the Raker Bill itself.

"Moreover, as explained by the Army Board to the Committee on Public Lands, should a controversy ever arise between the City and the irrigationists as to their respective rights, domestic consumption being the highest use to which water can be applied, under the laws of the State of California, the rights of the City will be paramount."

"Pending the construction of additional reservoirs by the irrigation districts, the Raker Bill provides that whenever the districts desire water in excess of that to which they are entitled under the terms of the bill, the City, on the demand of the districts, shall sell such quantities of stored water as may be needed for the beneficial use of the

districts—without impairing the supply for domestic requirements—at such a price", etc. Mr. Cory.

"It is provided, however, that the City may require the irrigation districts to purchase a minimum quantity of stored water, and shall not be required to furnish more than a maximum quantity, in any calendar year, the minimum and maximum quantities to be fixed by the Secretary of the Interior, keeping in mind the superior needs of domestic use."

"It is not within the range of probability that if during any year the City's supply of stored water should be brought so low as to make a water famine imminent, she should still be compelled to furnish water to the districts," etc.

The Raker Bill, though specifically stating that it does not interfere in any way with the laws of the State of California, grants the use of certain lands and rights of way in the Yosemite National Park and the Stanislaus National Forest only upon certain conditions which Congress imposed as entirely extraneous and having no relation whatever to California laws. The text of the bill with respect to these is as follows:

"Sec. 9, that this grant is made to the said grantee subject to the observance on the part of the grantee of all the conditions hereinbefore and hereinafter enumerated:

* * * * * * *

"(*b*) That the said grantee shall recognize the prior rights of the Modesto irrigation district and the Turlock irrigation district, as now constituted under the laws of the State of California, or as said districts may be hereafter enlarged to contain in the aggregate not to exceed three hundred thousand acres of land, to receive two thousand three hundred and fifty second-feet of the natural daily flow of the Tuolumne River, measured at the La Grange Dam, whenever the same can be beneficially used by said irrigation districts, and that the grantee shall never interfere with said rights.

"(*c*) That whenever said irrigation districts receive at the La Grange Dam less than two thousand three hundred and fifty second-feet of water, and when it is necessary for the beneficial use to receive more water the said grantee shall release free of charge, out of the natural daily flow of the streams which it has intercepted, so much water as may be necessary for the beneficial use of said irrigation districts not exceeding an amount which, with the waters of the Tuolumne and its tributaries, will cause a flow at La Grange Dam of two thousand three hundred and fifty second-feet; and shall also recognize the rights of the said irrigation districts to the extent of four thousand second-feet of water out of the natural daily flow of the Tuolumne river for combined direct use and collection into storage reservoirs as may be provided by said irrigation districts, during the period of sixty days immediately following and including April fifteenth of each year, and shall during such period release free of charge such quantity of water as may be necessary to secure to the said irrigation districts such four thousand second-feet flow or portion

Mr. Cory.

thereof as the said irrigation districts are capable of beneficially directly using and storing below Jawbone creek: Provided, however, That at such times as the aggregate daily natural flow of the watershed of the Tuolumne and its tributaries measured at the La Grange Dam shall be less than said districts can beneficially use and less than two thousand three hundred and fifty second-feet, then and in that event the said grantee shall release, free of charge, the entire natural daily flow of the streams which it has under this grant intercepted.

"(*d*) That the said grantee whenever the said irrigation districts desire water in excess of that to which they are entitled under the foregoing, shall on the written demand of the said irrigation districts sell to the said irrigation districts from the reservoir or reservoirs of the said grantee such amounts of stored water as may be needed for the beneficial use of the said irrigation districts at such a price as will return to the grantee the actual total costs of providing such stored water, such costs to be computed in accordance with the currently accepted practice of public cost accounting as may be determined by the Secretary of the Interior, including, however, a fair proportion of the cost to said grantee of the conduit, lands, dams, and water-supply system included in the Hetch Hetchy and Lake Eleanor sites; upon the express condition, however, that the said grantee may require the said irrigation districts to purchase and pay for a minimum quantity of such stored water, and that the said grantee shall be entitled to receive compensation for a minimum quantity of stored water and shall not be required to sell and deliver to the said irrigation districts more than a maximum quantity of such stored water to be released during any calendar year: Provided, however, That if the said irrigation districts shall develop sufficient water to meet their own needs for beneficial use and shall so notify in writing the Secretary of the Interior, the said grantee shall not be required to sell or deliver to said irrigation districts the maximum or minimum amount of stored waters hereinbefore provided for, and shall release the said districts from the obligation to pay for such stored water: And provided further, That said grantee shall without cost to said irrigation districts return to the Tuolumne River above the La Grange Dam for the use of the said irrigation districts all surplus or waste water resulting from the development of hydro-electric energy generated by the said grantee.

"(*e*) That such minimum and maximum amounts of such stored water to be so released during any calendar year as hereinbefore provided and the price to be paid therefor by the said irrigation districts are to be determined and fixed by the Secretary of the Interior in accordance with the provisions of the preceding paragraph.

"(*f*) That the Secretary of the Interior shall revise the maximum and minimum amounts of stored water to be supplied to said irrigation districts by said grantee as hereinbefore provided, whenever the said irrigation districts have properly developed the facilities of the Davis Reservoir of the Turlock Irrigation District and the Warner-Dallas Reservoir of the Modesto Irrigation District to the fullest practicable extent up to a development not exceeding in cost $15 per acre-foot storage capacity, and whenever additional storage has been provided by the said irrigation districts which is necessary to the economical utilization of the waters of said watershed, and also after water losses

and wastes have been reduced to such reasonable minimum as will assure the economical and beneficial use of such water. Mr. Cory.

"(*g*) That the said grantee shall not be required to furnish more than the said minimum quantity of stored water hereinbefore provided for until the said irrigation districts shall have first drawn upon their own stored water to the fullest practicable extent.

"(*h*) That the said grantee shall not divert beyond the limits of the San Joaquin Valley any more of the waters from the Tuolumne watershed than, together with the waters which it now has or may hereafter acquire, shall be necessary for its beneficial use for domestic and other municipal purposes.

* * * * * * *

"(*j*) That by 'the flow,' 'natural daily flow,' 'aggregate daily natural flow,' and 'what is naturally flowing,' as are used herein, is meant such flow as on any given day would flow in the Tuolumne River or its tributaries if said grantee had no storage or diversion works on the said Tuolumne watershed."

It will be noted that Paragraph (*f*) does not require the construction of any storage by the Turlock and Modesto Irrigation Districts, but, instead, requires the Secretary of the Interior to revise the maximum and minimum quantity of stored water referred to in Paragraph (*e*) whenever, and if, certain things occur.

One further excerpt is given from Mr. O'Shaughnessy's discussion:

"The Hetch Hetchy scheme has been the subject of very serious consideration by many engineers who, after comparing it with all other available sources of water supply, have endorsed it. The engineers who have questioned it, with the sole exception of those employed by the irrigation districts, have been the representatives of special competing interests, hoping to dispose of their own private holdings for their own private gains."

Mr. Van Norden expresses a radically different opinion. It certainly would be interesting, and doubtless very helpful to the local communities, to know what the consensus of opinion among local engineers really is. The writer suggests that Messrs. O'Shaughnessy and Van Norden co-operate in arranging for the San Francisco Association of Members of the American Society of Civil Engineers to carry out a confidential poll of the local Members and Associate Members of the Society—of which there are more than 130—or better yet, of all the societies which joined in holding the recent International Engineering Congress.

Turning now to the criticism, by Messrs. Rhodin, Sloan, and Brown, of the presentation in the paper of the Eel River source, it may be said that Eel River was given about as much attention as the Army Board gave it. Incidentally, the safe yield of this source, as given in Table 10, is exactly that found by the Army Board, which, however, also finds that with a conduit of 225 000 000 gal. daily capacity, and utilizing considerable local storage, the safe yield could be

Mr. Cory. increased to 200 000 000 gal. daily. The writer has not checked these figures. Should the East Bay cities continue to keep aloof from San Francisco and its water plans, as Mr. Sloan suggests, they would probably find Eel River the most attractive and available mountain supply—possibly at the lowest cost per thousand gallons of any distant water under any arrangement.

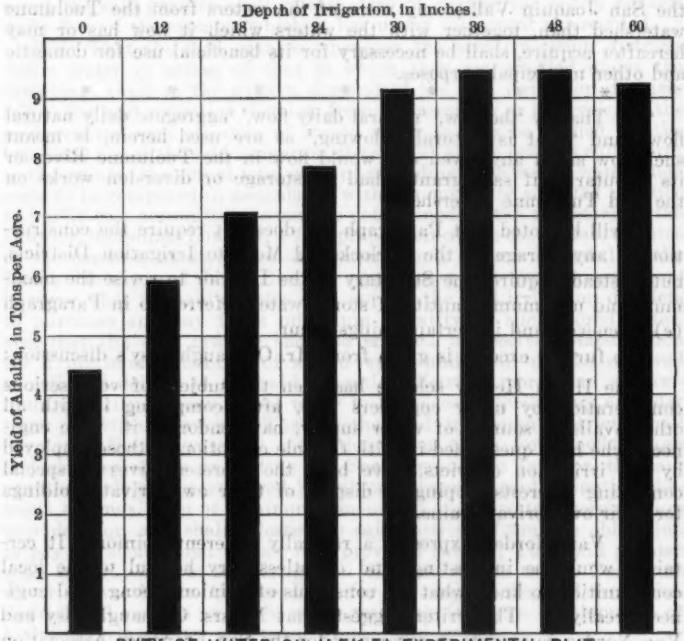

FIG. 29.

Mr. Grunsky and others refer to the local sentiment regarding Sierra water. It undoubtedly is strong, which is interesting, and so is the reason for its existence. Sacramento, situated at the very edge of the Sierras' western foot-hills, is overwhelmingly in favor of filtered Sacramento River water. Human nature in the two cities is doubtless practically the same, so that the difference in the public sentiment in this regard is doubtless due to the respective com-

munities having had engineering advice along different lines. The real enthusiasm with which San Francisco people greeted Mr. Grunsky's Tuolumne project in 1902 was probably because it was the first concrete plan put forward under the new charter, whereby the "yoke" of the Spring Valley Water Company might be thrown off and that corporation crumpled. Mr. Cory.

The writer has been much interested in the expressions of opinion concerning the water needs of the 300 000 acres in the Turlock and Modesto Irrigation Districts. However, summarizing the essential facts, concerning which there seems to be general consent, it appears that the adaptation of most of the area is alfalfa, dairying, and stock; that six irrigations per annum are required for maximum economical yield; that the soil is, broadly speaking, rather sandy; and that the mean annual rainfall over the territory is 11 in., of which little, and frequently none, occurs in the cropping season.

Consequently, the writer sees no occasion to modify his ideas on the subject expressed in the paper, and especially the opinion that ultimately the total irrigation needs per gross acre in this area and in the Imperial Valley will prove to be practically the same—about 3.33 acre-ft. In reference to this matter, Fig. 29* is instructive.

Since writing the paper, more than a year and a half ago, the following important developments in the water situation have occurred:

1.—The jurisdiction of the Railroad Commission has been extended to the control of all public utilities, inside as well as outside of municipalities.

2.—The city officials and the Spring Valley Water Company agreed upon a sales price for all the latter's property which it was deemed advisable to purchase. At a special election, the proposition received a majority but not the necessary two-thirds affirmative vote.

3.—An election was held in the East Bay cities for the formation of a municipal water district, but the proposition was defeated.

4.—The Richmond Municipal Water District voted against authorizing a bond issue for bringing water from the Sacramento River.

5.—The Marin Municipal Water District has condemned before the Railroad Commission the property of the Marin Water and Power Company and the North Shore Water Company. The companies, feeling that the price fixed by the Railroad Commission was too low, have appealed to the State Supreme Court.

Paper No. 1353

THE PICAZA BRIDGE

By A. A. Agramonte, Assoc. M. Am. Soc. C. E.

Synopsis.

This paper contains a description of a reinforced concrete bridge spanning a part of the Valley of the Salada River, in the Province of Buenos Aires, Argentine Republic, and, together with ten other bridges and some smaller works, was built under the direction of the Drainage Commission of the Province of Buenos Aires.

The bridge consists of a central span of 26 m. (85 ft.) and six lateral spans of 28.5 m. (93.5 ft.) each. The central span consists of a floor system suspended by steel tension members from two concrete arches each of which is reinforced with a structural steel skeleton arch, and tied by a steel chord to take up the thrust. The hangers are bolted to the chord, and all the tension members are encased in concrete. Roller bearings at one end provide for expansion and contraction. Two transverse arches supply wind bracing and help to make the structure rigid.

Each lateral span consists of three continuous reinforced concrete beams resting on three supports. The central supports are concrete pylons, and are fixed. The end supports are masonry pillars; and steel bearing plates, on pillars and beams, face to face, allow free temperature movement. The floor and sidewalk are carried on a transverse beam and slab system.

A brief description is given of the drainage works and the structures involved, and then the Picaza Bridge is described, the working organization, the foundations, the materials, the labor, the finish, the progress, and the costs.

General Description of the Drainage Works.

The Region.—The Drainage Commission of the Province of Buenos Aires is a board of land owners having charge of the design and execution of works for the relief of the southern part of that Province, a region subject to inundation at intervals of from 10 to 15 years. This region is a great plain dipping gradually toward the Atlantic Ocean on the east, and receiving the discharge of the flashy hill streams, or "arroyos", which drain the uplands and "sierras" on the west. Below this upland region watercourses disappear from lack of fall, and, in the whole area subject to inundation, there is only one river, the "Rio Salada", with a continuous channel, and this is utterly inadequate to convey the flood flow from its own water-shed. The area subject to inundation is approximately 39 750 sq. km., or more than 9 700 000 acres.

The Project.—To ameliorate the disastrous effects of the periodical inundations in a country with no natural drainage channels, a number of canals have been projected and built for the double purpose of, first, carrying the average flood flows of the "arroyos" directly to the sea at a relatively high level, and secondly, receiving the drainage of the lower zones through numerous sluice-gates at a low level after the discharge of the flood flow of the "arroyos". Complete flood prevention would be economically impossible. The system takes a normal flow of 46 000 000 cu. m. per day (18 800 cu. ft. per sec.).

These canals are of many sections and lengths, but a description of them would be foreign to the object of this paper. It is sufficient to state that they consist in general of a central excavated section from 2 to 4 m. (7½ to 15 ft.) deep and from 10 to 30 m. (33 to 108 ft.) wide and a flood section formed by lateral dikes from 1.5 to 4 m. (5 to 13 ft.) above the ground level, and from 80 to 300 m. (262 to

984 ft.) in effective width between the dikes. Three of the canals are more than 130 km. (80 miles) long, one is more than 260 km. (160 miles) long, and there are sixteen others of varying lengths, and thousands of miles of laterals. The total length of the main canals is 1 005 km. (624 miles) and the contents are more than 30 000 000 cu. m. (39 240 000 cu. yd.). The total cost to date has been $40 000 000 of official paper money, equivalent to more than $17 400 000 in gold.

Control and Accessory Works.—To discharge flood waters under control, and conserve the natural watercourses where convenient, structures of the following types were built:

1.—The works at the entrance of the derivation canals consisted of entrance gates controlled by machinery, and waste-weirs or gates (generally automatic) to discharge the excess flow to natural channels. The gates and appurtenances are of steel and bronze; the structures are of reinforced concrete with steel skeletons, hoop-bound brickwork or hardwood ("quebracho"), according to location. Piling and sheet-piling were used where necessary. Works of this type have been constructed at the origin of nine canals.

2.—Sluice or drainage gates were placed at appropriate places in the length of the canals, and provide for the drainage of the low-level zone. The gates and appurtenances are of steel and bronze, but hardwood gates are also used. All types are automatic. There are 114 of these structures.

3.—Relief openings are provided with gates operated by machinery, and serve to supply or to empty large "lagunas" or natural reservoirs. The gates, etc., are of metal and the structures are mainly of reinforced concrete. There are five of these openings.

4.—Waste-weirs take the water from the canals to natural watercourses, at places of strategic importance. These are automatic, and generally of reinforced concrete or hoop-bound brickwork. There are six of these weirs, exclusive of those at the head-works.

5.—Inverted siphons are used to pass low-level streams under the canal where it has been found necessary to maintain such channels for the drainage of certain districts. There are three of these.

6.—Bridges have been built wherever traffic has required them. They are of varying spans, types, and materials. Table 1 gives information regarding all the bridges built.

SECTION F-H

GENERAL PLAN
PICAZA BRIDGE
OF THE
DRAINAGE COMMISSION
OF THE
PROVINCE OF BEUNOS AIRES
ARGENTINA

The Picaza Bridge.

Location.—The Picaza Bridge, 5 km. (3 miles) from the City of Dolores on the highway to Sevigné, in common with all the works described, was designed by the Technical Office under the supervision of the late Engineer Director, Mr. Charles Nyströmer. The execution of the work, together with that of ten other bridges and minor structures, was assigned to the writer under Mr. Humphrey W. Cooper, Chief Engineer. The Inspector General of all the works of the Drainage Commission was Mr. Leonard Cooper.

General Description.—The bridge is composed of one central span of 26 m. (85 ft.) and six lateral spans of 28.5 m. (93.5 ft.) each, all in reinforced concrete. The central span consists of a floor system suspended by steel tension members from two concrete arches each of which is reinforced with a structural steel skeleton arch and tied by a steel chord to take up the thrust. The hangers are bolted to the chord, and all the tension members are encased in concrete. Roller bearings at one end enable the arch to move with variations of temperature. Two transverse arches provide for wind bracing and help to give complete rigidity to the structure.

Each lateral span consists of three longitudinal continuous reinforced concrete beams resting on three supports; the central support is a concrete pylon, and is fixed. The end supports are masonry pillars. Steel bearing plates on pillars and beams, face to face, allow free temperature movements. A transverse beam and slab system carries the floor and sidewalk.

Organization.—As far as possible, the work was done by using both piecework and bonus systems. Ordinary day labor was used where unavoidable on a very small proportion of the whole. The writer, although having under construction many other bridges at the same time, made a point of directing all important work personally, a difficulty which may be realized when it is stated that it required a two days' trip to reach some of the other bridges. A general foreman and a time and storekeeper completed the permanent force in charge of the work.

Those who examine the statement of costs of this bridge should bear in mind that the general foreman had to be instructed in his duties while on the work, as no sober, experienced, and reliable con-

crete men having the requisite knowledge and skill were to be found in Buenos Aires when the work was commenced. Further, laborers in summer desert the work to go to harvesting, with the expectation of higher wages. Form carpenters, also, have to be taught on the work, and, as they know that new men do not acquire the necessary experience in a short time, they soon become very urgent in their demands for increased wages. In brief, reinforced concrete construction was a continual struggle, first to teach the men and afterward to hold them on the work, and this was aggravated by the difficulty of obtaining reliability in foremen and timekeepers, a greater problem than it may seem from a distant viewpoint.

For the foregoing reasons labor costs should be higher than in regions more favored in the respects indicated; nevertheless, the writer may claim that they represent fair costs for that part of the country, as the work was done for 30% less than the lowest prices bid for it by a contracting firm, and 50% less than the next highest bid (including all administrative charges, etc.). The costs given

to imitate stone. † On branch canals.

may be taken as representative of work of this class in the Province of Buenos Aires at the present time.

Excavation of Foundations.—The excavation was in hard clay, which was shoveled into Decauville cars and transported by horse traction about 200 m. (650 ft.) to the lateral dikes of the canal. The spoil from the cylinder excavation followed the same route.

Foundations.—The foundations of the lateral piers and abutments were of 1:3:5 concrete, with crusher screenings instead of sand. The materials were brought from stock piles, about 100 m. (328 ft.) from the axis of the bridge, in Decauville cars to a portable mixing platform placed as near the work as possible. The stone and screenings were measured in the cars. The concrete was mixed by hand and placed directly from the platform. Two mixing platforms were used, and were moved as needed. The stone had to be washed well before it was used, as it had been stored in an exposed position for more than a year, and was full of dirt. Water was provided by a windmill pumping to two tanks having a capacity of 12 cu. m.

(3 170 gal.), and then conveyed in a pipe line, parallel to the bridge, with outlets at intervals of 14 m. (46 ft.).

The foundations of the pylons are of reinforced concrete, and in these the materials and their proportions are the same as in the plain concrete. In all the foundation concrete, granite rubble was embedded in order to economize in crusher stone, because, owing to a variation in the original design, a large surplus of this material was available.

Each pier supporting the central span rests on a reinforced concrete slab, and this rests on two reinforced concrete cylinders which were sunk to hard clay 9 m. (29½ ft.) below ground level. The internal diameter of each cylinder, at the steel cutting edge, is 3 m. (9 ft. 10 in.), decreasing to 2 m. (6 ft. 6¾ in.) at the top. The lower section of each cylinder was built to a height of 3 m. (9 ft. 10 in.) and at once sunk to the ground-water level, then the upper section was built and the sinking completed. The several steps in the work were as follows:

1.—Excavation, to ground-water level, of area of slab;
2.—Construction of lower section of Cylinder I;
3.—Construction of lower section of Cylinder II; (the wooden framework over the excavation for handling buckets, etc., was erected while the cylinders were being built);
4.—Sinking Cylinder I and then Cylinder II to sand (2 m. below ground-water level), using picks, and shoveling the earth to the platform and to cars, a hand-diaphragm pump being used for unwatering;
5.—Construction of upper sections of Cylinders I and II;
6.—Sinking Cylinder I below the 2-m. level, using two buckets suspended from a pulley raised alternately by a hand-winch, the buckets dumping directly into cars, the unwatering being done with a 6-in. centrifugal pump with a steam motor.

Two men below kept the buckets in continual operation, and a crew of three alternated at the winch and dumped the buckets into the car. In ordinary hard but sandy soil the progress was about 1 m. of depth per day. There were no difficulties until, at a depth of 4 m. (13 ft.) below the ground-water level, quicksand was encountered. At the end of each pumping period, after a little excavation, there

was an inrush of fine sand which flowed like mud and filled the excavation at least 1 m. in depth. This material choked the flexible suction hose of the pump and caused delay. The constant inflow of sand began to undermine the upper crust and great fissures radiating from the cylinder excavation began to appear. Progress was stopped, although only 1 m. of fine sand separated the cutting edge from the hard clay; and, though the writer himself entered the water, it was difficult to restore the "morale" of the men.

The remedy for the trouble was simple. An inner cylinder of galvanized-iron sheeting was driven around wooden bracing rings, each sheet being driven into the hard clay. The inner cylinder was well cleaned, the pump suction pipe was hoisted, and the lower 2 m. (6½ ft.) of the cylinder concreted under water, using a wooden tremie to place the concrete, the tremie being raised by the hand-winch when necessary. The upper section was packed with sand and capped with concrete.

A reinforced concrete platform resting on the two cylinders completed the foundation.

Abutments and Piers.—The abutments and piers are of brick masonry, with 1:3 mortar. In part of the work washed stone crusher dust was used instead of sand, and with satisfactory results. In the central piers about 20% of the volume was rubble masonry filler, owing to the surplus of rubble already mentioned.

Pylons.—The pylons are of 1:2:4 reinforced concrete, using 1 to 2-in. stone. They were built simultaneously with the piers, and all were at least 1 month old before the forms for the superstructure were erected. The columns were built in one continuous operation, allowing time for thorough settling of the wet concrete by working on two or more alternately, pouring sections 1 m. (3¼ ft.) high at a time.

Superstructure.

Forms for Lateral Spans.—The forms were designed to obtain the greatest recover value for use elsewhere. Two complete sets (each for one 28-m. (91.86-ft.) span) were used in rotation with three sets of uprights. This arrangement allowed for continuous work by the carpenters.

Movement of Materials.—Sand and stone were measured in the Decauville cars at the stock piles and transported to the central part

of the bridge where two low-level mixing platforms received the stone after it had passed over an inclined slatted platform on which it was washed thoroughly with a hose. The sand was discharged directly to the platforms. Arrangements were made to permit the discharge of sand or stone to either platform, and the stone-washing crib or inclined platform was divided into four compartments, each having a capacity of 1 cu. m. (35.3 cu. ft.) so that washing could be carried on always two batches ahead of the mixing. No difficulties were experienced at any time with this arrangement.

Cement and sand, in the proportions of 1:2, were mixed by hand, dry, turning the mixture three times, until it was of uniform color; then two parts of washed stone were added, and the concrete was mixed with plenty of water until the mass was of uniform jelly-like consistency.

A 50-ft. steam derrick with a bucket containing ½ cu. m. (11.7 cu. ft.) received the concrete directly from the mixing platform and hoisted it to an elevated distribution trestle parallel to the bridge.

The concrete was dumped from the bucket of the derrick into a Decauville car on the trestle, and the car ran by gravity to the point of discharge, where it was placed by a movable dumping box, 2 by 2 by 0.30 m. (6.56 by 6.56 by 1 ft.), with adjustable, steel chute (a 0.30-m. smokestack sawed in two). There was no trouble of any kind with this arrangement, and concrete was in place within half an hour of mixing. Two men handled the car and derrick bucket, and dumped the concrete into the dumping box; two men below tamped the concrete, and controlled the discharge of the chute; and a fifth man acted as general emergency man, a very important position, as the conditions of discharge varied continually. It may be noted that all concrete was mixed very wet, and all forms were drenched before they were filled, although, of course, all surplus water was drained off.

One elevated trestle was used for one-half of the bridge, and after concreting, it was taken down and re-erected for the other half. The truck was about 2 m. (6.56 ft.) above the bridge floor and about 1 m. (3.28 ft.) from the bridge railing over which it was necessary to chute the concrete. The concrete was in the proportions, 1:2:2. The sand was a very good, coarse, river sand from Uruguay. Fine granite chippings were used for the lower parts of the beams, where

FIG. 1.—PYLON COLUMNS AND BRICKWORK PIERS AND ABUTMENTS, PICAZA BRIDGE.—SECOND MONTH.

FIG. 2.—FORMS AND REINFORCEMENT OF HALF OF ONE LATERAL SPAN BEFORE ADJUSTING REINFORCEMENT.

the complicated reinforcements demanded a very fine aggregate, and a 1 to 2-in. stone in the remainder of the concrete.

With one gang of 10 men working alternately on the two mixing platforms, it took 3 days to concrete one 28-m. (91.86-ft.) span, the work being executed in the following order:

1a.—All reinforcement was securely placed, tied, and braced.

b.—All forms were washed and well drenched.

c.—All concrete adhesion surfaces (pylons) were picked and grouted with neat cement.

d.—All surfaces of contact over masonry pillars were rubbed with clay to prevent adhesion.

e.—Sliding bearing plates for beams to rest on pillars were placed and greased face to face.

2.—First Day.—Longitudinal beams were concreted from the pylon outward, on both sides to the center of the 14-m. (45.93-ft.) span, leaving a vertical joint near the center of each beam.

3.—Second Day.—The vertical joints were washed, brushed lightly, and grouted with neat cement. The beams were finished to the end of the span.

4.—Third Day.—After riveting the railing and adjusting the horizontal hand-rail to exact position (it is embedded in the concrete of the sidewalk), the slab was concreted, beginning at one end and finishing at the other.

Great care was taken throughout to ensure bond by washing and grouting, and every precaution was taken against the displacement of reinforcement or of concrete already set.

Central Span.—Entirely new forms were required for the central span. The steel reinforcing arch was utilized as much as possible to support the forms for the arch, and the transverse beams and slabs were supported from below.

The work was executed in the following order:

1.—The steel reinforcing arch was erected and bolted. This was done with the customary falsework, which was used subsequently to support the floor forms. The arches were braced by wooden struts and tied with wire while being adjusted and bolted.

2.—The forms for the concrete arch and suspended floor system were built, using material from the old forms where possible.

3.—The arches were concreted with 1:2:1½ concrete, using fine stone. One arch was completed in one day, beginning at the haunches and working toward the crown, with alternate pourings, so as to distribute the weight symmetrically, thus no construction joints were necessary.

4.—The floor-beams, slabs, and sidewalks were concreted in the order named, and the pavement and sidewalk finished as that of the rest of the bridge.

5.—One month after concreting the arches, in order to allow for subsequent deflections, and with all dead load in place (paving block, sand, etc.), the hangers or suspension members were concreted, and afterward the longitudinal tension members.

After concreting the lateral span of the first half of the bridge, the masonry on that side was continued upward and, at the same time, granite curbing and compressed asphalt tile sidewalk were placed.

Pavement.—The concrete floor was water-proofed with a 1-cm. (0.39-in.) coating of a coal-tar sand mixture placed hot and ironed. All expansion joints were filled with asphalt. Surface and sub-surface drains were placed, and the floor of the bridge was paved with Swedish granite block paving sets, consisting of 0.10-m. (3.9-in.) blocks, placed so as to form a mosaic fan-shaped design. These blocks were laid on a 7-cm. (2¾-in.) cushion of sand, and the joints were filled with coal-tar after the pavement had been consolidated thoroughly.

The abutments were paved with ordinary 15-cm. (5.9-in.) block paving resting on a concrete raft slab, to allow for subsequent settling. Although the fill on which the pavement rests was consolidated thoroughly by watering and tamping, it had settled 5 cm. (2 in.) one year after it was laid. It had been given a super-elevation of 7 cm. (2¾ in.).

Concluding Masonry, Ornamental Designs, etc.—After concreting the central span, the masonry of the central pillars was finished and the ornamental designs at the crowns of the arches and at the haunches were added by grouting behind plaster of Paris negatives held in place by bracing and wiring. Granite mosaic work was used to fill the decorative triangular panels above the haunches of the arches.

and it may be of interest to note that this mosaic gives a very effective and beautiful contrast to the concrete.

The ornamental brackets on the side spans were cast in Buenos Aires on a foundation of expanded metal. They are hollow, and very carefully hammer-dressed to resemble cut stone. They were tied in place to the sidewalk reinforcement through tubes, purposely left in the concrete, which were afterward grouted from above and sealed.

Surface Finish.—All masonry above the cornice level was plastered with 1:2 sand mortar, and, after hardening, was hammer-dressed to give the appearance of cut stone. The cornices were plastered with the same mortar but combed with a fine steel comb, giving an imitation of cut stone. This method is used effectively in the Argentine on nearly all buildings of architectural merit.

Below the cornice level a rough granolithic surface was secured by first making longitudinal grooves with cement mortar and, when these were hard, plastering between the grooves with granite chips, and cleaning the surface subsequently. This produces a granite surface which reflects the light and is broken by smooth horizontal lines—a combination which contrasts well with the smooth pylon columns.

The exposed sides of the side spans were left rough and scrubbed with wire brushes; then a coarse sand mortar was rubbed on the rough surface, using small grindstones for that purpose; two coats were applied, the second on the first before it had set. In this way a hard impermeable rough surface was obtained, which, at a distance of 3 m., can hardly be distinguished from the hammer-dressed portions. It may be pertinent to call attention to the fact that a surface of uniform color and texture was desirable because the necessary use of different cements on different spans had produced a variety of shades, not at all pleasing, and this finish corrected this defect.

The upper and lower surfaces of the arches were finished smooth. The hangers and tension members were plastered on the picked concrete, in order to obtain the curves of the design. The sides of the arches were well picked and then plastered with fine granite chippings, and wire-brushed 12 hours afterward to remove the cement coating. A fine and very satisfactory granolithic surface was obtained. The under surfaces were simply washed with cement to produce a uniform tone.

In all cases the objects have been to obtain a uniform tone, to break up the light, and, at the same time, to avoid monotony in the appearance of the different classes of surface. It may be said that these objects have been achieved, although, as the granite used is of exactly the same color as the cement, far greater and more pleasing contrasts could have been obtained with an aggregate of a different color.

The appearance of the bridge is pleasing, and it is of interest to note that although a near view gives the idea of massiveness, at a distance of 1 km. (3 280 ft.), the impression conveyed is that of extreme lightness.

General Observations.—After a year of sun, frost, and floods, it has been noticed that there are no structural cracks in the work. A few have appeared in the mortar plastering, but always near or at expansion joints or bearings of the concrete beams, and these, in all cases, have been due to the plastering of the brickwork not having been isolated completely (by cutting) from the movable beam surfaces.

The effect of variations in temperature on the length of the beams is very noticeable. On a cold night a movement of 1 cm. (0.39 in.) is easily seen on the lateral spans, and the central span contracts 2 cm. (0.79 in.). The range of temperature is from 0° to 35° cent., but the most sudden changes are in the early spring and late fall when freezing temperature at daybreak is followed by high temperature at noon, or within 5 hours.

Progress According to Schedule.—A schedule of work was made and adhered to as closely as possible, but there were many causes for delay. For instance, there was a compulsory slow-down of 2 months caused by a general strike of the railroad locomotive drivers; materials were delayed in arrival, the rate of work was lessened, and, in fact, all work was affected. Another cause of delay was in the sinking of the cylinders, which was not as rapid as expected, owing to the difficulties mentioned. This was an important feature because the completion of the central piers controlled the time of finishing the spans resting on them. There were also minor delays caused by modifications in design, lack of paving materials (which were imported from Sweden and were late in arrival), and for 3 months at the beginning of the work there were not enough competent carpenters for form work. The work began in January, 1912, and

traffic was passing over the bridge in December of the same year, although all the surface treatment had not then been completed.

Costs.

Table 2 shows the scale of wages paid. The working day varied from 7 hours in winter to 10 hours in summer. Italian, Spanish, Greek, and Bulgarian laborers were employed.

TABLE 2.—Scale of Wages Paid.

Duty.	Wages or Salary.	Equivalent American Currency.
General foreman	$220.00 and bonus, average $280.00	$123.00
Concrete foreman	125.00 " " " 150.00	66.00
Concrete laborers	3.20 " " " 4.50	1.98
Cylinder laborers	4.00 " " " 5.50	2.42
Carpenters	6 to $7 " " " 8.00	3.52
Masons	5 to 7 " " " 8.00	3.52
Time and storekeeper	120.00 120.00	52.80

Tables 3, 4, 5, and 6, showing the costs, are self-explanatory. Owing to the fact that the costs of materials, transportation, and overhead charges not incurred on the work itself, were not kept by the writer, he regrets that he cannot detail them as he has the labor costs, but the totals are correct, and he trusts that they may give an idea of the cost of the work under given conditions in a distant country. To an American engineer, the proportion of money spent on purely esthetic grounds in a prairie region may seem to be too great, but such seems to be the custom of the country, and perhaps, eventually, on broad grounds, it may be regarded as proper for permanent structures of this type.

TABLE 3.—Costs of Labor and Materials on Picaza Bridge.

Class of work.	Cost.	Units.	Cost per Unit.		Observations.
			Pesos.	U.S. gold dollars.	
Excavation, foundations	791.16	1 023.3 m.	0.77	0.33	Average depth, 1 m.; average haul, 150 m.
Excavation, sinking cylinders	2 015.08	283 m.	7.12	3.03	To 9 m. below surface. Haul, 200 m. includes pumping.
Cylinders, sand filling	71.71	50 m.	1.43	0.61	Including transport and loading at 200 m.
Concrete:—1 : 3 : 5					
Foundations	984.03	301 m.	3.27	1.39	Mix and place, including some reinforcement.
Cylinders	886.17	174 m.	5.09	2.16	Including forms, reinforcement and plastering.

TABLE 3.—(*Continued.*)

Class of work.	Cost.	Units.	Cost per Unit.		Observations.
			Pesos.	U.S. gold dollars.	
Reinforced Concrete :—					
1 : 2 : 2 and 1 : 2 : 1½					1 : 2 : 1½ only in arches and hangers, 48.3 m.
Reinforcement, prepare.	670.37	110 tons.	6.09	2.59	Bending and transporting from shop to place.
" place...	980.75	110 tons.	8.91	3.79	Place and tie.
Forms, erect and take down	5 751.12	732 cu. m.	7.86	3.34	Two sets used three times for lateral spans, one set for central span, cost 50% more.
Concrete, mix and place	2 964.71	732 cu. m.	4.05	1.73	Central span = 125.3 m.
Masonry :					
Brickwork, 1 : 3 cement mortar	4 545.19	1 009.3 m.	4.50	1.91	250 tons of rubble utilized in masonry, including piers, abutments, and ornamental pillars.
Plastering on Brickwork :					
Imitation granite	1 349.96	529.2 m.	2.55	1.08	Granite chippings brushed, broken horizontally by smooth channeling.
Imitation fine cut stone...	2 180.50	623 m.	3.50	1.49	Plastered 1 : 2 fine sand and combed with fine comb.
Rustic	191.10	273 m.	0.70	0.30	Rough cast plastering.
Finishing Concrete Surfaces :					
Plastered and rubbed	986.64	793 m.	1.24	0.53	Plastered and rubbed with grind-stone, 2 coats.
Fine plastering	1 627.50	465 m.	3.50	1.49	Plastered 1 : 2 fine sand and combed with fine comb.
Imitation granite	267.00	89 m.	3.00	1.27	Granite chippings brushed, broken horizontally by smooth channeling.
Cement wash	338.40	1 692 m.	0.20	0.09	Applied with brush, 2 coats.
Hammer-dressing Mortar Surfaces	584.48	244 m.	2.39	1.02	On plaster 80% ; on narrow concrete bands, 20 per cent.
Modifications :					
Tie-wall pylons	481.75	161 m.	29.92	12.72	Between columns, including picking sides of columns and reinforcement.
Transverse arches	119.63	3 m.	39.87	16.94	Central span wind bracing, including forms, reinforcement and plastering.
Ornamental Castings :					
Central span	269.40	12 No.	22.45	9.54	Place negatives, grout with 1 : 2 mortar, and finish surfaces.
Lateral-brackets	335.76	84 No.	3.99	1.70	Place, grout, and plaster bevels, etc.
Steel Hand-railing :					
Rectify	212.00	380.1 m.	0.56	0.24	Made in Buenos Aires, received bent.
Place and rivet	604.76	380.1 m.	1.59	0.68	Including bracing while concreting sidewalks.
Paint, 3 coats	484.79	271 tons.	1.79	0.76	
Pavement :					
Water-proofing concrete..	396.00	990.2 m.	0.40	0.17	Coal-tar and sand applied hot and ironed.
Surface and sub-surface drains	76.42	36	2.12	0.90	16 surface cast-iron inlets ; 16 sub-surface 2½-in. pipes, and 4 inlets, cast iron and brick, on abutment areas.

Paper No. 1354

PEARL HARBOR DRY DOCK*

By H. R. Stanford,† M. Am. Soc. C. E.

With Discussion by Messrs. Charles Evan Fowler, Harrison S. Taft, W. F. Frear, P. L. Reed, Frederic R. Harris, Leonard M. Cox, W. H. Pretty, J. R. Baterden, Herbert E. Bellamy, B. C. Laws, Edward Box, and H. R. Stanford.

Synopsis.

The object of this paper is to inform those interested in engineering matters regarding the peculiar difficulties and problems which the construction of the Pearl Harbor Dry Dock has involved.

The paper contains a topographical and geological description of the location which was chosen for the dock, a review of the Congressional authorizations and appropriations for the work, a brief description of the plans and methods of construction originally adopted, an outline of the changes which were made in dimensions and details as the work proceeded, and a description of the field troubles which were experienced and of the experiments and tests conducted to determine the best means for their correction.

The paper concludes with a description of the plans and methods which were finally adopted and under which the work is now proceeding.

A paper on the Pearl Harbor Dry Dock at this time may on first thought be considered premature, inasmuch as little progress has been

* Presented at the meeting of September 1st, 1915.

† Corps of Civil Engineers, U. S. Navy; Chief of Bureau of Yards and Docks, Navy Department.

made toward actual completion, but a description of the work from its inception to date seems to be justified, in view of the numerous and peculiar construction difficulties which have been experienced, its military importance, its interest as an engineering project, and the recent resumption of operations on radically modified plans. It must be borne in mind, while reviewing the history of this project, that we now have the inestimable advantage of "hindsight" for our guidance, and that the problems involved should be weighed accordingly.

Location.

Pearl Harbor is in the southern part of the Island of Oahu, of the Hawaiian group, and is a body of water of irregular shape, formed by several lochs or arms of the sea. The depth of the water in the harbor generally varies from 35 to 50 ft., and these depths are well maintained to the shore line. The land surrounding the harbor is comparatively level, at an elevation of about 12 ft. above mean low tide. The tidal movements average about 1 ft. 2⅜ in. The channel connecting the harbor with the sea was naturally shallow and rather crooked, but, as a result of dredging operations completed in 1912, it now has a least depth of 35 ft. over an entrance width of 600 ft. and a minimum width of 500 ft. within the entrance, with curves eased to permit of the safe passage of battleships. The dredging operations required the removal of 4 645 000 cu. yd. of material, throughout a channel 5 miles long, at a cost of $3 296 000, and are of engineering interest because of the successful manner in which the work was conducted over the entrance bar, where there was a heavy sea swell at all times.

The area included in the Pearl Harbor Station was acquired in February, 1904, by the Bureau of Equipment of the United States Navy Department, under its authority to purchase land required for the storage of coal.

The Act of Congress, approved May 13th, 1908, making appropriations for the naval service, includes an item reading:

"The Secretary of the Navy is hereby authorized and directed to establish a naval station at Pearl Harbor, Hawaii, on the site heretofore acquired for that purpose; and to erect thereat all the necessary machine shops, storehouses, coal sheds, and other necessary buildings, and to build thereat one graving dry dock capable of receiving the

largest vessels of the Navy, at a cost not to exceed two million dollars for said dry dock."

The location of the naval station is especially favorable because of the proximity of natural deep water to the large areas of low-lying level land which are included within the boundaries of the property. The ground conditions are fairly good for the support of heavy concentrated loads, but sub-surface operations, which require the exclusion of ground-water, are costly because of the porous character of the soil. The railroad and highway facilities between Honolulu and the station are excellent, and the existence of the large and convenient commercial center is of inestimable value to the station as a base for labor and supplies.

The first general outline plan for the development of the Pearl Harbor Naval Station, following its Congressional authorization, was submitted in a report dated July 22d, 1908, by a Board of which Rear-Admiral Seaton Schroeder, U. S. N., was senior member. The location for the dock shown on this plan was slightly changed in its axial and transverse position, and the design was directed for a dock having a length of 1 140 ft. with an intermediate caisson to provide two chambers, 564 and 536 ft. long, respectively, in accordance with the recommendation of C. W. Parks, M. Am. Soc. C. E., Civil Engineer, U. S. N., and the Bureau of Yards and Docks, by authority of the Navy Department dated November 19th, 1908. The location for the dock was again changed by the Navy Department on March 19th, 1909, by moving the dock on its axis a distance of 200 ft. inshore, as a result of the great apprehension expressed by bidders regarding the dangers and difficulties which would attend the building and maintaining of a coffer-dam in the deep water in front of the dock entrance.

Geological.

The Island of Oahu is of volcanic origin, and consists of an elongated hilly or mountainous section, about 45 miles in length, lying in a southeast and northwest direction, with a surrounding fringe of low land formed by accretions of coral and volcanic origin. Pearl Harbor is on the south shore of the island, within the fringe formation, and is about 8 miles from Honolulu.

The geological conditions at the site of the dock are of very great importance in the consideration of the difficulties which have been

experienced in the construction of the work, and therefore warrant a careful description. The surface soil, to depths exceeding those reached by any part of the dock, is either volcanic or organic sediment. The volcanic sediment or tuff beds result from the intermixture of ashes and volcanic stones fallen from the air, with pebbles and sands made of hard lava washed in from the island valleys, the combination being, in some cases, re-arranged by water into beds of sand, or mud, or gravel. The material of organic origin consists of coral skeletons or shells ranging from hard reef, as originally deposited by coral animals, to broken and disintegrated material heaped together by the waves or assorted into gravels, sands, and muds, or intermixed with volcanic materials. There is no regular stratification of the material, and its lack of uniformity and its wide variation between the limits of hard and soft may be judged from the penetration records of various pairs of adjacent piles (piles in any one pair not more than 4 ft. apart) which were driven to refusal in the bottom of the dock excavation, as follows: 9 and 23 ft.; 5 and 26 ft.; 6 and 25 ft.; 3 and 24 ft.; 22 and 37 ft.; 11 and 35 ft.; 15 and 43 ft.; 5 and 32 ft.; 13 and 21 ft.; 11 and 22 ft.; 10 and 27 ft.; and 14 and 26 ft.

Described in detail, the soil comprises the following elements:

Rock Types:

Volcanic Tuff.—A hardened volcanic ash.

Volcanic Grit.—A hardened coarse volcanic sand.

Volcanic Agglomerate.—A hardened volcanic gravel made of angular fragments formed by explosion.

Coral Rock.—Material of an old reef still in place.

Soft Deposits:

Volcanic Mud.—A fine-grained aggregate of lava minerals formed by the wash of river or sea.

Volcanic Sand.—An aggregate of volcanic minerals, generally dark-colored, formed by wash of river or sea, and assorted to grains of fairly uniform size. The grains will be more or less rounded, according to the distance they have traveled and the amount of wear to which they have been subjected.

Volcanic Gravel.—Like volcanic sand, but coarser and of variable sizes. A true volcanic gravel containing pebbles of basaltic lava larger than the fragments in the Pearl Harbor tuffs, and

occurring in their vicinity, is presumptive evidence of the existence of a river channel from the hills, as it would be impossible for shore currents of the ocean to carry pebbles of ledge rock from any point on the shore of the island where such rock is exposed to the waves, along the coast and into the tortuous channels of Pearl Harbor without reducing them to sand or mud.

Coral Mud.—A fine-grained, white, yellow, or buff mud, made of crushed coral and shells.

Coral Sand.—Assorted grains of coral and shells of fairly uniform size.

Coral Gravel.—Washed fragments of coral and shells, more or less rounded, and more or less mixed with sand.

Mixed Deposits:

Tuff-Coral Mud.—A fine-grained aggregate of particles of tuff and of tuff minerals, mixed with particles of coral and shells.

Tuff-Coral Sand.—An aggregate of volcanic sand and coral sand mixed.

Tuff-Coral Gravels.—An aggregate of volcanic gravels and coral gravel mixed.

Basalt-Coral Gravel.—An aggregate of coral gravel and gravel made of partly rounded fragments of basaltic lava.

The softer classes of the foregoing materials become a mud or sand when soaked with water, but the solid coral and tuff rocks maintain their integrity. The volcanic deposits effervesce in dilute hydrochloric acid only in such proportion as they contain infiltrated carbonate vein material, whereas the corals, coral sand, and coral mud—which are composed almost wholly of carbonate of lime—effervesce very strongly.

An examination of the side slopes of the practically completed excavation for the dock, and of boring records, indicates a close resemblance between the underlying materials at the dock site and formations exposed in road cuts in the vicinity, except that the former are thinner-bedded and more uniformly horizontal, because of their greater distance from their source. Figs. 1 and 2 are photographs with notations which illustrate the principal formations. Borings for Artesian wells in the Pearl Harbor district reveal the great

thickness of these coral and volcanic deposits below sea level, thus clearly indicating a history of gradual submergence and explosive volcanic activities, with occasional uplifts of the deposits.

Design.

The usual modern dry dock of the graving type is essentially a masonry prism resting in an earth excavation. Inward earth and water pressure against the side-walls and upward hydrostatic pressure on the bottom are the principal forces which the prism must be designed to resist. The dry dock prism thus economically becomes a gravity arch structure, made of concrete, which depends on the weight of its material and arch action for stability. Water-tightness is incidentally obtained by the proper proportioning of the concrete ingredients. The main problem to be solved in the construction of a dock, therefore, depends on obtaining impervious monolithic and homogeneous concrete of permanent character, and having maximum unit weight combined with an ordinary degree of strength and hardness.

These comparatively simple requirements formed the basis of the design which was originally adopted for the Pearl Harbor dock. They assumed that concrete could be placed under the favorable dry and open conditions which usually obtain, and that earth friction on the sides of the prism, combined with the natural resistance of the underlying soil to infiltration, would warrant a reduction in the concrete in the prism to a quantity which would weigh somewhat less than the equivalent of a full upward hydrostatic pressure on the bottom.

As the work progressed, it became apparent that the usual open coffer-dam method of construction could not be followed, because of the porous and water-bearing condition of the soil. Arrangements were then made whereby foundation piling with heads buried in the bottom concrete was provided, and the contractor was permitted to place not to exceed the lower 8 ft. of bottom concrete by the under-water method. There was no provision, however, for any material enriching of the mix to offset losses and difficulties which the under-water method involved. The futility of this procedure was demonstrated by the defects in the 6 284 cu. yd. of concrete which had been placed to an average thickness of 6.52 ft. over a section of 180

FIG. 1.—ROADSIDE CUTTING, SHOWING MATERIALS FOUND IN EXCAVATION FOR PEARL HARBOR DRY DOCK.

FIG. 2.—ROADSIDE CUTTING, SHOWING MATERIALS FOUND IN EXCAVATION FOR PEARL HARBOR DRY DOCK.

lin. ft. at the inner end of the dock site, and which was partly exposed when the surrounding coffer-dam was unwatered to a depth of 37.3 ft.

The next modification in the work consisted in changing the ingredients in the under-water concrete, making the mix 1 part cement, 2 parts sand and 3½ parts broken stone, and in which one-third of the sand was silicious, from the mainland, and two-thirds were screenings from crushed lava rock. This richer mixture was placed to an average thickness of 6.75 ft. over a section of dock 240 ft. long adjacent to the inner section in which the lean concrete had been used. The under-water concrete in this section was placed in forms approximately 12 ft. square, and it was arranged that adjacent blocks should be finished with upper surfaces in planes separated by about 12 in., in order that an effective bond could be made between this lower concrete and that which was to be placed later when completing the floor. The collapse on February 17th, 1913, occurred in this second section, but, as all records agree that the concrete was of excellent quality, it may be asserted that the attempt to obtain satisfactory concrete in deep water by the tremie method was successful, and that the collapse was chargeable to other causes.

By this time it was recognized that local conditions demanded, not only unusual and expensive methods of construction, but also that the concrete should be exceptionally rich in quality with increased quantity, and that extensive metal reinforcements were necessary in the bottom to provide effectively for irregularities in the supporting power of the underlying soil. The recent change in contract recognizes all these needs; it provides a structure which is heavier than the water displaced; practically eliminates all concrete which must be placed under water; permits of thorough inspection; introduces substantial steelwork to relieve any probable tensile stresses in concrete; and provides for the independent settlement of seventeen practically equal portions of the dock before combining them into a single unit, thereby insuring the completed dock against settlement cracks and leakage.

Appropriations and Contracts.

Specific Congressional authorization is necessary before undertaking the construction of any public works improvement required for the Navy. The dry dock for Pearl Harbor was originally au-

thorized in an Act, approved May 13th, 1908, which fixed the limit of cost at $2 000 000. This limit was increased to $2 700 000 and then to $3 486 500 by Acts approved June 24th, 1910, and August 22d, 1912, in order that the dock could be made 1 000 ft. long and 110 ft. wide, to accord with the dimensions of the Panama Canal locks. The limit of cost was again increased by an Act, approved June 30th, 1914, and made $4 986 500, to provide for radical changes in plans to obtain a more substantial dock and reduce building hazards.

Contracts for naval public works always contain a provision whereby the Government reserves the right to make such changes in the contract, plans, and specifications as may be deemed necessary or advisable. The actual modification of a contract to cover a change of magnitude is accomplished with a document called a "Supplemental Agreement", which is acknowledged by the surety, accompanied with additional bond, and finally executed in the same manner as the original contract. Contracts and supplemental agreements for the Pearl Harbor Dry Dock in accordance with the Congressional authorizations previously cited, have been made as follows:

Original contract, dated July 22d, 1909, awarded to the San Francisco Bridge Company of San Francisco, Cal., provided for a dock to receive a vessel having dimensions not to exceed: length, 581 ft. 0 in.; beam, 105 ft. 4 in.; and draft, 31 ft. 8⅜ in., with clearance of 3 ft. 0 in. over the entrance sill, to cost $1 760 000.

Supplemental Agreement "A", dated June 27th, 1910, enlarged the dock to receive a vessel having dimensions not to exceed: length, 792 ft. 0 in., and beam, 113 ft. 4 in., and added $544 000 to the original contract cost.

Supplemental Agreement "B", dated August 5th, 1911, provided foundation piles for the dock, with an increase in contract cost of $150 643.22.

Supplemental Agreement "C", dated January 2d, 1913, enlarged the dock to receive a vessel 1 000 ft. long, provided for enriching the bottom concrete, and added $711 842.50 to the contract cost.

Supplemental Agreement "D", dated November 19th, 1914, made radical changes in the details of the plans and specifications, without materially changing the dimensions of the dock, and added $1 261 350 to the contract cost. This addition, together with sums added on

account of various minor changes, makes the total obligation under the contracts amount to $4 442 115.43.

Plate V shows the general outline dimensions of the dock as it has developed under the foregoing changes.

Supplemental Agreement "C" is considered of particular interest to the engineer because of the special provision which it contains to place full responsibility more definitely on the contractor for the completion of the dock, and also because of the relation which this condition created between the contractor and the Government's engineer in charge at the time of the collapse of the work on February 17th, 1913, and further because of its bearing on the negotiations preliminary to resuming work on radically changed plans subsequent to the collapse.

Prior to the execution of this supplemental agreement there had been a conference between the Chief of the Bureau and the contractors, during which the latter were informed that inasmuch as it was proposed to modify the contract to provide a dock of increased length, which would practically obligate the entire amount authorized for the construction of the dock, it would be necessary for the contractor to agree definitely to complete the work without any further increase in contract price, regardless of any mishaps or accidents which might subsequently be experienced. It was explained to the contractor that a primary reason for entering into contract for the construction of the dock was to insure the completion of the work within the amount authorized by Congress. In order to avoid interference with the operations of the contractors, which would tend to relieve them of their responsibility, it was arranged that the greatest possible latitude would be given in conducting the work; in other words, that it would be left largely with them to determine such details as the quantity of water which should be added in mixing concrete as affecting its consistency, the dimensions of the forms into which tremie concrete should be placed, the manipulation of the tremie, etc. In accordance with this understanding regarding responsibility, the following paragraph was included in the supplemental agreement forming a part of the contract:

"That it is specially understood and agreed that the party of the first part may elect any adequate methods or details of methods of construction to be employed in the construction of said dry dock and its appurtenances, and that the said party of the first part assumes full and complete responsibility for the adequacy of the materials specified and of the methods and details of methods of construction to

be employed and for the successful and satisfactory completion of the entire work in all its parts, and agrees to make good at its own expense any defect or inadequacy of the materials as herein or elsewhere specified and any defective or unsatisfactory work: *Provided,* That all materials and workmanship and the adequacy of all methods and details of methods of construction shall, as contemplated by the contract, be subject to the approval of the party of the second part. And it is further specially understood and agreed that all items of extras, damages, claims, time allowances, or other matters that have been or might be the subject of differences of opinion or dispute are merged in this agreement and satisfied and extinguished by the consideration herein stated and that no claim shall hereafter be presented or entertained on account of anything connected with the construction of said dry dock and appurtenances occurring or existing prior to the date of this agreement."

Having in mind this special provision of the contract and the circumstances which led to its adoption, let us consider the position of the officer in charge representing the Government during the several days immediately preceding the collapse of the work on February 17th, 1913. During this period the cribbing and sheet-piling protecting the section which was being unwatered had been showing increasing evidence of distress, up to the time of the collapse, when the bottom was almost exposed and in condition for the placing of concrete, each yard of which would have reduced the building hazard. It should also be noted that the conditions in this crib at this time were not very different from those which had existed several months before when Crib No. 1 was unwatered to practically the same depth without disastrous results.

The officer in charge, an experienced engineer, was fully cognizant of the extreme hazard of the situation prior to the collapse, but, knowing the responsibility on the contractor for the safe conduct and completion of the work, any interference on his part, based solely on his individual judgment, would probably have involved serious responsibility on the Government in defending his action as affecting the period required for the execution of the work, and also the contractors' expenditures. The great distance of the work from the Bureau and from other engineers with whom the officer in charge might have consulted, combined with the brief period during which the weakness of the coffer-dam was in evidence, together with knowledge of the contract provisions regarding the contractors' responsibility, resulted in placing the officer in charge in a very difficult position. Now that

the occurrence with all its details is a matter of history, it is very easy to conclude that some other course of procedure than that actually followed might have been better and proper; but, under the circumstances, it is doubtful if others would have done differently.

The negotiations between the Government and the contractors following the collapse of the work, were based on the claim of the contractors that the contract plans were insufficient to provide a safe and satisfactory dock; no claim was made on account of losses sustained. The contractors claimed, however, that it was the plans which were at fault, and that the Government was responsible for the plans; they further represented that any radical change in plans could not be considered as proper within the meaning of the paragraph on changes as contained in the contract, and that if such radical changes were desired it would be optional with the contractors as to whether they should agree to them. It was undoubtedly desirable that the contractors should proceed with the work in view of the valuable experience which they had acquired and in order to utilize the plant which had been assembled; the contractors on their part were anxious to proceed because of their business and professional standing. The Department of Justice, after a review of the contract, states, in an opinion given January 5th, 1914,

"Of many building contracts, I have never seen one that so persistently declared for full responsibility on the contractor during the course of construction."

In view of the foregoing conditions, the Bureau of Yards and Docks, which is charged with the design and construction of naval public works, felt constrained to withhold any proposal to adopt new methods or plans for the work until after the Secretary of the Navy should decide in favor of a stronger, more reliable, and more costly structure. This decision was reached by the Secretary early in April, 1914, after obtaining the advice of the late Alfred Noble, Past-President, Am. Soc. C. E., and various members of the Corps of Civil Engineers of the Navy; the general design for the dock which was subsequently adopted was then presented by the Bureau during the same month.

Field Operations.

Excavation.—Excavation for the dock was made with a dipper-dredge to a depth of from 35 to 38 ft. below low-tide level, and completed

to the required depth with a hydraulic dredge fitted with a rotary cutter. Dredging was begun in October, 1909, and practically completed in December, 1910. The material was loosened in advance of dredging by blasting, which required drilling 3-in. holes, from 6 to 10 ft. apart transversely, and somewhat farther apart longitudinally with the dock; about 50 lb. of 40% gelatine was used for each hole.

Coffer-Dam.—The open coffer-dam method of construction was adopted by the contractor when work was first started, and was followed up to the time that operations were temporarily suspended in February, 1913. The distance between the side-walls of the coffer-dam was about 148 ft., which was sufficient to include the full width section of the dock. The length of the coffer-dam was divided into sections by transverse bulkheads. The excavation required within a section of coffer-dam was completed in advance of building the coffer-dam. Interior cribwork was used for bracing the coffer-dam walls, as was done in constructing the dock at Mare Island, California, where the same contractors' superintendent was in charge. The walls of the coffer-dam were of 12-in. square timbers; two pieces of timber were first bolted together to form a unit, after which beveled-edged strips of 3-in. stock were secured to opposite edges of each unit, two strips on one edge and one strip on the opposite edge, the bevels and spacing of the strips being arranged so as to obtain a dove-tailed joint connecting adjacent units.

The cribwork comprised essentially a system of six horizontal tiers; each tier was of transverse and longitudinal timbers 12 ft. from center to center; a vertical timber standing on a concrete footing piece at the bottom of the excavation bound together the several tiers at each panel point of each bent; the upper tier was about 3 ft. above low-tide level, and the lower tiers were at intervals of 11.5, 10.1, 9.0, 8.0, and 8.0 ft., respectively; the first, second, and sixth tiers and the vertical members were of 12-in. square timber, with an 18 by 22-in. wale for the second tier; the third tier was of 14-in. square timber, with two 12 by 24-in. wales; the fifth tier was of 16-in. square timber with two 14 by 24-in. wales; the fourth and fifth tiers were braced together at each bent by intermediate transverse bracing to form Howe trusses; there was one line of diagonal bracing for each bent. Figs. 3 and 4 are photographs showing the coffer-dam and crib.

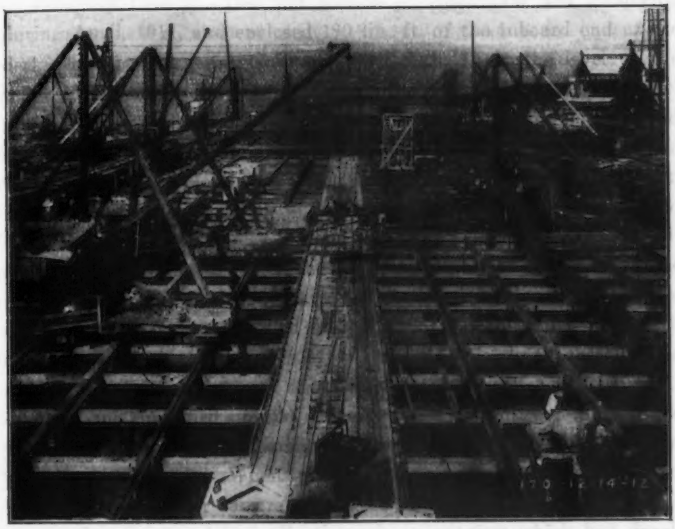

FIG. 3.—COFFER-DAM, PEARL HARBOR DRY DOCK.

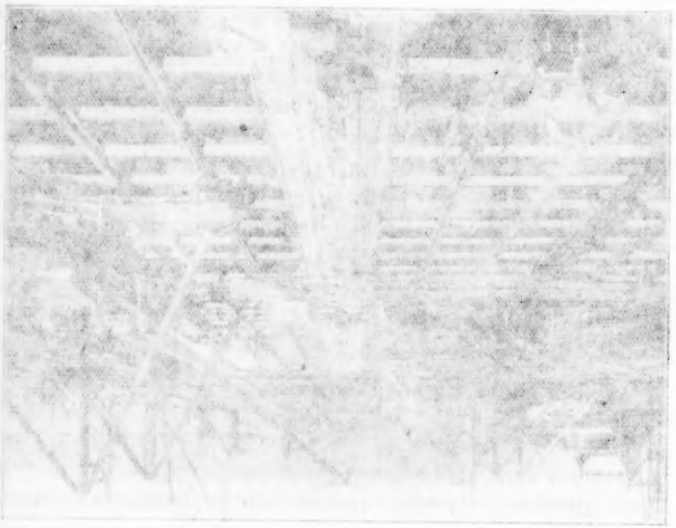
FIG. 4.—CRIBWORK IN COFFER-DAM, PEARL HARBOR DRY DOCK.



Pumping Crib I.—The first section of coffer-dam was completed during April, 1911, and enclosed 180 lin. ft. of the inboard end of the dock. Unwatering was begun on April 29th, 1911; the level of the water inside the coffer-dam was held from 2 to 3 ft. below sea level until May 3d while leaks in the sheet-piling were being located and stopped by divers. During the next 2 days the water was lowered to 16 ft. below sea level, when a slight rising was noted in the crib. On May 5th the water surface was lowered to 17.5 ft. where it was held until May 8th, when it was lowered to 21 ft. The cribwork gave evidence of serious distress when the depth of 21 ft. was reached, and the pressure was relieved by quickly reducing the head to 16 ft. The depth of 16 ft. was maintained until May 10th, when it was increased to 17 ft.; within a few hours after reaching this depth there was a sudden increase in the rate of leakage into the coffer-dam, until it exceeded the combined normal capacity of 18 500 gal. per min. of the three 15-in. and one 8-in. drainage pumps, and caused the suspension of pumping operations. When pumping was discontinued, the water level within the coffer-dam rapidly arose nearly to tide level, the water apparently entering principally through an opening which had developed in the sheet-piling. Pumping was resumed on May 11th, but, after 2 days, using all four pumps, it was found impossible to unwater below 16 ft. due to the excessive leakage into the coffer-dam, and further effort to unwater the section was therefore abandoned.

Very peculiar and alarming movements in the sheet-piling and cribbing had been noted during pumping operations; on May 5th, under a head of 17.5 ft., the cribbing in the southwest quarter of the coffer-dam had risen about 4 in. and the sheet-piling in the south half of the west side had risen 3½ in.; on May 8th, with a head of 17.5 ft., the portions of crib and sheet-piling which had previously shown greatest movement had risen an additional ¾ in., and some rising had been noted over all other parts of the coffer-dam except in the northeast corner; after the head had been increased to 21 ft. on May 8th portions of crib and sheet-piling had come up 5½ in. farther and were rising so rapidly, having reached a maximum of from 9½ to 11⅛ in., according to different observers, that the coffer-dam would have failed had the head not been quickly reduced; there was an immediate settlement of 1 in. in the sheet-piles and crib when the head was reduced to 16 ft.; the crib settled 6½ in. and the sheet-piling 2½ in. when the coffer-dam

was flooded on May 10th; the maximum permanent distortion noted on May 18th, after the coffer-dam had been flooded for 5 days following the suspension of pumping operations, was a rise of 6 in. in part of the sheet-piling and a settlement of ¾ in. in the crib. Observations on the test column (base area, 4 sq. ft., loaded with 16 tons, and placed within the area of the coffer-dam to determine the bearing value of the soil) showed that the column rose slightly as the water in the coffer-dam was lowered, and settled when it was flooded.

Piling and Seal.—Experience acquired during the first attempt to unwater a section of the coffer-dam resulted in contract modifications, dated August 5th, 1911, which provided a piling foundation for the dock and permission to place concrete by the under-water method. The reason for the latter provision, and the limitation specified for its use, are given in the following quotation from the contract:

"For the purpose of forming a seal that will facilitate the unwatering of the excavation, concrete may be deposited under water. For this purpose tremies shall be used * * *. The depth of concrete so deposited shall not exceed 8 feet."

It was anticipated that the piles, which were to be 4 ft. from center to center longitudinally and about 3.5 ft. from center to center transversely, would have an average length of 39 ft., of which 4 ft. would be embedded in the concrete bottom of the dock, leaving 35 ft. for the depth of penetration. The piles would thus serve both as anchors and supports. The anchorage value of the piling naturally combined with the weight of the concrete seal to withstand the upward hydrostatic pressure on the concrete when the coffer-dam was pumped out; hence the greater the pile anchorage the less concrete required by the under-water method, and, as concrete placed through tremies was much more expensive than when deposited in the open, the less the cost to the contractors.

Contract payments on account of piling were based on the number of linear feet actually driven, and it was provided that the thickness of concrete in the bottom of the dock might be reduced 1 ft. to allow for the swelling of the ground which the driving of piles might produce. The reduction in the thickness of the concrete, as affecting the strength of the dock, was justified, inasmuch as the anchorage of the piling against hydrostatic uplift was more than equivalent to the weight of the concrete eliminated. The original plans for the dock

required that a 12-in. layer of rich concrete, 1 part cement to 4 parts stone, with enough sand to fill its voids, should form the outermost portion of the bottom and side-walls to serve as an impervious skin to exclude the percolation of ground-water into the interior mass of leaner 1:6½ concrete. The adoption of the under-water method for depositing concrete rendered it impossible to place these two grades as at first intended, and an average mix of about 1:3.4:6.19 was substituted, to be used alike for both tremie and dry concrete.

It was actually found that piles could not be driven to the depths anticipated, and the records show that the average penetration of the 1 966 piles driven in Section I, which includes 180 lin. ft. of dock at the inboard end, was 23.78 ft.; the 2 537 piles driven in Section II, which included 240 lin. ft. of dock adjoining Section I, have an average penetration of 20.53 ft.; the 2 652 piles driven in Section III have an average penetration of 28.49 ft.; and the 1 720 piles driven in Section IV have an average penetration of 28.20 ft. Pile driving was completed in Section I on September 11th, 1911; in Section II on December 2d, 1911; in Section III on June 13th, 1912; and in Section IV on January 11th, 1913. Piles are not yet driven for Section V. It was observed with surprise that, notwithstanding the close spacing and large number of piles driven, the surface of the ground between the piles showed little evidence of swelling or rising.

Placing concrete for the bottom of the dock and to form a seal in the bottom of the coffer-dam surrounding Section I was begun in October, 1911. It was soon found that the 1:3.4:6.19 mix was too lean to make satisfactory tremie concrete, and the use of a 1:3:5 mix was authorized on October 20th, 1911. Concreting through tremies in Section I was completed on January 4th, 1912; the 6 284 cu. yd. of concrete which were placed had an average thickness of 6.52 ft.

Pumping Crib I, Second Attempt.—The second attempt to unwater Section I of the dock was started on January 18th, 1912. The water surface was gradually lowered by four pumps having a nominal capacity of 18 500 gal. per min. A depth of 34.3 ft. was reached on January 26th, when it was noted that a portion of the cribbing of the coffer-dam near the west wall had risen 1 in. No further rise was noted in the coffer-dam 8½ hours later, when the head had been increased to 36.3 ft. The concrete in the bottom along the side-walls of the coffer-dam was exposed at this depth and found to be of generally poor quality.

and very poor in places. On January 28th the crib and sheet-piling near the center and west side of the coffer-dam had risen another inch, making a total of 2 in.; on January 28th, after the rise in the crib had increased to 2½ in., the head was reduced to 26 ft., where it was maintained until February 1st, while 160 tons of rock ballast were placed over the bottom at the places where the rise in the crib had been greatest. The head was then increased to 36.0 ft. without any further rise of the coffer-dam being observed. On February 2d the head was increased to 37.3 ft., and the removal of poor concrete and the substitution of richer concrete was started. Several leaks developed through the concrete seal on February 3d, and the pumps were stopped. The coffer-dam was completely flooded by leakage within 16 hours after pumping was stopped. On February 5th the crib had settled to within 1 in. of its original position on January 18th. On February 11th pumping was again started, and a head of 37.5 ft. had been obtained at 11.30 A. M. on February 13th when large leaks developed through the concrete, which resulted in pumping operations being stopped at 3.10 P. M., and the coffer-dam being allowed to fill. The defects in the concrete were apparently due to lack of experience in using the tremies under the conditions which prevailed and to the use of too lean a mixture, causing the impregnation of the concrete mass with sea water.

Concrete Changes.—The troubles experienced during the second attempt to unwater Section I led to contract changes dated January 2d, 1913, which required the removal of all the defective concrete previously placed in Section I, and provided for the use of a very much richer mixture for tremie-placed concrete. A considerable quantity of silicious sand from the California Coast was necessary for this new mixture. The increase in the dimensions of the dock covered by this contract change was made possible by the increase in the limit of cost which had shortly before been authorized by Congress.

The concrete seal made with the new and richer tremie mixture was completed in the coffer-dam surrounding Section II of the dock on January 20th, 1913. This section comprised the 240 lin. ft. of dock adjoining Section I, around which the coffer-dam had been constructed while concreting and pumping operations had been going on in Section I. The seal contained 8 555 cu. yd. of concrete having an average thickness of 6.75 ft. after making allowance for the volume

of embedded pile heads. In placing this seal, advantage was taken to provide a positive bond to connect the tremie concrete and the upper mass which was to be placed after unwatering; this bond was considered necessary to prevent the possible lifting of the upper mass of concrete in case leakage through the tremie concrete should produce internal disrupting pressures, and was to be accomplished by finishing the surfaces of the tremie concrete in adjacent forms at different levels; as the tremie concrete was poured into forms, each covering areas about 12 ft. square, this arrangement resulted in producing a surface somewhat like a checker board in which the surface of each 12-ft. square was approximately 12 in. above or below the surfaces of adjacent squares, thereby giving an effective dove-tailed bond with the superimposed concrete which was to be placed at a later date.

Pumping Crib II.—A final attempt to unwater the combination timber and concrete coffer-dam surrounding Section II of the dock was started on February 6th, 1913. Table 1 gives the depth of unwatering from day to day, as well as the corresponding total rise of crib noted at two points of maximum uplift.

" 17	2.40 P. M.	36.50 "	.....	0.18
" 17	3.00 P. M.	Coffer-dam failed at about this time.		

The outer row of concrete blocks along each side-wall of the coffer-dam was exposed on February 16th, and the quality of the concrete was found to be excellent. About sixty 2½-in. vertical drain pipes had been placed in the concrete seal during its construction; these drains,

distributed over the area of the coffer-dam, all flowed to some extent when the coffer-dam was pumped out, and a few of them flowed freely; a piece of hose connected with the upper end of one of the free-flowing drains filled with water to within 1 ft. of low-tide level, indicating that the water pressure beneath the concrete seal was nearly equal to sea pressure at corresponding depth, and probably would have been fully equal to sea pressure had the other drainage pipes in the vicinity of the one under test been closed. It will be noted from Table 1 that the rate of uplift of the coffer-dam was not very great until the morning of February 17th, and did not begin to be very alarming until about 1.00 P. M., when it was evident that the work was in grave danger. One of the pumps was stopped at 1.45 P. M. and all pumping was stopped at 2.00 P. M. The coffer-dam collapsed at about 3.00 P. M.; the crib lifted several feet at the time of failure, according to the statements of eye-witnesses.

The portions of the coffer-dam surrounding Sections I and III of the dock failed with the failure of the crib in Section II. Fortunately, no lives were lost, nor was any one injured. Figs. 5 and 6 are photographs showing the work after the collapse. Comparison of soundings taken on the surface of the concrete seal before the collapse with those made 6 weeks thereafter, indicates local vertical displacements varying from a maximum uplift of 9.4 ft. to actual settlements. It has not been practicable to obtain any accurate knowledge regarding the movements in the piling which supported and anchored the seal, but it seemed safe to conclude that it had all been rendered unreliable and therefore practically worthless, and the recently approved plans require its entire renewal.

Pressures.—The weight of excavated material removed from the dock site probably varied from about 2 500 lb. per sq. ft. at the entrance end, where the natural surface was nearly 10 ft. below low-tide level, to about 4 500 lb. per sq. ft. at the inner end of the dock, where the original surface was 14 ft. above tide level. The side slopes of the excavation stood at a very steep angle after the completion of the excavation. These slopes did not seem to be materially disturbed as a result of the coffer-dam, pile-driving, and pumping operations, or by the collapse of the coffer-dam, and there is no evidence of any material subsidence of the side banks. The submerged weight of the concrete in the completed dry dock structure, if considered as uniformly dis-

FIG. 5.—WRECK OF COFFER-DAM AFTER COLLAPSE, PEARL HARBOR DRY DOCK.

FIG. 6.—WRECK OF COFFER-DAM AFTER COLLAPSE, PEARL HARBOR DRY DOCK.

tributed, will be about 2 000 lb. per sq. ft. of area; if the weight of the side-walls is considered separately from the weight of the floor, the unit weight, per square foot of area covered, will be about 3 300 lb. under the side-walls and about 1 400 lb. under the floor. With the dock pumped out and containing a ship of maximum dimensions, the uniformly distributed weight on the underlying soil, in excess of full hydrostatic uplift corresponding to low-tide level, will be about 1 500 lb. per sq. ft.; if the weight of the side-walls is considered separately from that of the floor and ship, the weights imposed under the side-walls and floor will be about 2 300 and 1 100 lb. per sq. ft., respectively.

It is of interest to compare the maximum depths of 37.5 and 37.05 ft. obtained on February 11th, 1912, and February 17th, 1913, in the coffer-dams of Section I and Section II, respectively, with the depth of 38 ft. between extreme high-tide level and the floor of the completed dock. Although the concrete which had been placed in Section I was only 6.52 ft. thick, and in Section II only 6.75 ft. thick, as compared with the thickness of 16 ft. required for the finished dock, and although the side-walls which would tend to anchor the floor and reduce its span had not been started, it will be seen that the partly completed floor in both cases had been called on to resist nearly the maximum uplift which could be brought to bear on the completed structure.

Full hydrostatic uplift on the bottom of the dock at the time of collapse would average about 3 100 lb. per sq. ft. of area. Forces resisting this uplift were developed by the weight of concrete in the seal, the anchorage of the piles, the weight of coffer-dam materials, the weight of water remaining in the coffer-dam, the arch action developed in the concrete seal, and the arch action developed in the layer of soil which was penetrated by the piles; these resisting forces averaged, per square foot, about 1 012 lb. on account of concrete, about 1 080 lb. on account of piles (using 54 lb. per cu. ft. as a conservative estimate for the submerged weight of soil), about 170 lb. on account of coffer-dam, and about 300 lb. on account of water remaining in the coffer-dam; no accurate estimate can be made of the arch resistance in either the concrete or soil; from this analysis it would appear that arch resistance to uplift amounted to about 538 lb. per sq. ft. at the time of collapse.

Although the foregoing analysis based on averages is very interesting, it is extremely doubtful whether the figures given represent the facts due to the following conditions: the dish-shaped form of the concrete seal, which made the unit hydrostatic uplift along the sides much less than under the middle portions; the great differences in the thickness of the concrete blocks which composed the seal and in the length of the anchoring piles; the difference in the depth of water remaining in the coffer-dam at different points, which varied from about nothing at the sides to a depth of several feet over the middle portions; and to the irregular character of the soil underlying the coffer-dam. It is very probable that the collapse of the coffer-dam originated at some particularly weak point in the seal or in the underlying soil, and that local weakness resulted in general failure.

Concrete.

Materials.—The Island of Oahu, unfortunately, does not abound in materials which are best suited for making concrete. Gravel is not obtainable, and there is no silicious sand. A very satisfactory broken stone is made by crushing a hard blue lava rock, but it has been found very difficult to locate a quarry having the necessary capacity and transportation connections, and at the same time being comparatively free from the unsuitable grade of porous rock which is known locally as "puka-puka". There is an abundance of coral and sea-shell beach sand, locally called "Waianae", but its use for concrete is objectionable because of its uncertain chemical stability when incorporated in the completed dock. Screenings from the stone crusher are used to a large extent in lieu of sand. Cement is obtained from California mills.

Sand.—Fig. 7 indicates graphically the character of the natural sands and of the artificial substitute products, obtained either from the stone crusher or by mixing, which were considered as available for use in making concrete. Curve 1 represents a silicious building sand of medium fineness obtained from Puget Sound. Curve 2 represents the screenings obtained through a ¼-in. sieve from the rock crusher which supplies broken stone, and includes crusher dust. Curve 3 represents a combination of the materials used for Curves 1 and 2 mixed in proportion of one part of the former with two parts of the latter. Curve 4 represents crusher screenings through a ¼-in. sieve and is the

same as shown by Curve 2, except that dust passing a 30-mesh sieve is removed. Curve 5 represents coral sand obtained from the vicinity of the work. The mixture represented by Curve 3 was adopted as the best, and was used in making the successful tremie concrete. A combination of equal parts of the materials represented by Curves 4 and 5 shows practically the same characteristics as the mixture represented

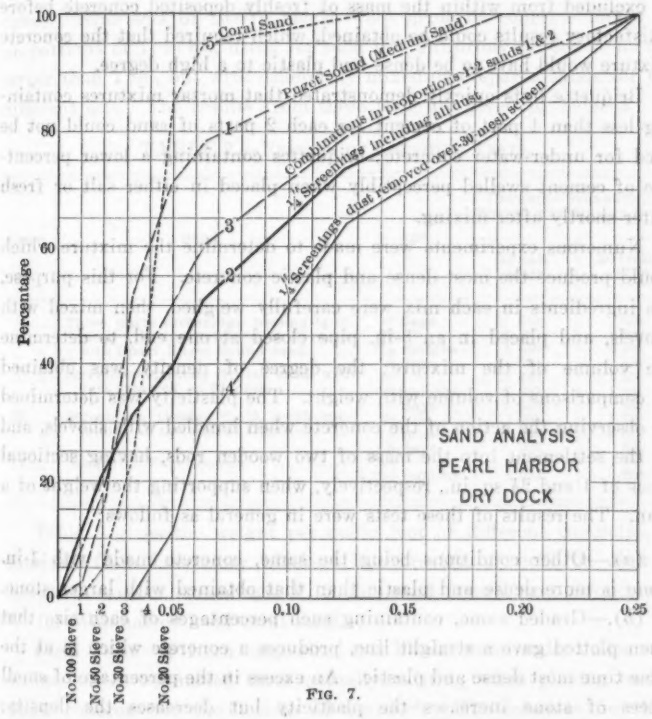

FIG. 7.

by Curve 3 for grains retained on a 20-mesh sieve, but the former contains only 7% of smaller grains which pass this sieve, as compared with 38% of the smaller-sized grains in the latter mixture; the larger percentage of small grains is necessary to obtain concrete of the best quality.

Mixture.—Examination of the concrete which was first placed by the under-water method revealed such serious defects as to render it

practically worthless. There was apparently a lack of bond throughout the mass due to general permeation with sea water, forming a soft, white, chalky substance with the cement which encased the particles of sand and pieces of broken stone in such way as to prevent consolidation. Chemical analysis showed that this chalky substance consisted principally of sulphates. It was evident that salt water would have to be excluded from within the mass of freshly deposited concrete before satisfactory results could be obtained, which required that the concrete mixture would have to be dense and plastic to a high degree.

Briquette tests quickly demonstrated that mortar mixtures containing less than 1 part of cement for each 2 parts of sand could not be used for under-water concrete; briquettes containing a lower percentage of cement swelled perceptibly when placed in either salt or fresh water shortly after mixing.

Numerous experiments were made to determine the mixture which would produce the most dense and plastic concrete. For this purpose, the ingredients in each mix were carefully weighed, then mixed with shovels, and placed in an 8-in. pipe closed at one end, to determine the volume of the mixture; the degree of density was obtained by comparisons of volume with weight. The plasticity was determined by observing the action of the concrete when handled with shovels, and by the settlement into the mass of two wooden rods, having sectional areas of 1 and 2½ sq. in., respectively, when supporting the weight of a man. The results of these tests were in general as follows:

(*a*).—Other conditions being the same, concrete made with 1-in. stone is more dense and plastic than that obtained with larger stone.

(*b*).—Graded stone, containing such percentages of each size that when plotted gave a straight line, produces a concrete which is at the same time most dense and plastic. An excess in the percentage of small pieces of stone increases the plasticity but decreases the density, whereas a deficiency in the small sizes has little effect on the density but reduces the plasticity.

(*c*).—Density and plasticity are a maximum when using Puget Sound sand mixed with screenings which contain crusher dust; elimination of any part of the crusher dust affects the results adversely. One part of Puget Sound sand with from two to three parts of screenings with dust gives the maximum plasticity, but the density is not

affected materially when the proportions are varied between the limits of 1:1 and 1:3.

(*d*).—Mixtures in proportions of 1:2.5:4 are more plastic than those of 1:2:4, but are not as dense; 1:2:4 mixtures are more dense than those of 1:2:3½, but are not as plastic.

Laboratory Tests.—A series of 132 crushing tests were made on 6-in. cubes. Nine sets of twelve blocks were made of concrete mixed in proportions of 1:2:3.5, using for each test uniformly graded stone not larger than 1 in., but with differently mixed or prepared sands for the different sets. The results from these tests are given in Table 2.

TABLE 2.—RESULTS OF CRUSHING TESTS.

Class.	Sand.	Age.	Crushing Strength, in Pounds per Square Inch:	
			In salt water.	In fresh water.
I....	Three parts screenings passing ½ in. mesh with dust retained on 30-mesh, with 1 part Puget Sound sand.....	3 days	685	620
		28 "	1 435	1 320
		2¼ months	1 850	2 285
II....	Screenings passing 3/16-in. mesh with dust retained on 30-mesh.....	3 days	590	470
		28 "	1 280	1 230
		3 months	1 985	1 985

Table 3 gives the weight per cubic foot of different concretes, as obtained from laboratory blocks. For brevity, cr. will be used to designate crusher screenings, P. S. for sand from Puget Sound, and W. for Waianae or local coral sand.

Field Tests.—Fifteen large-sized test blocks were made, under conditions which resembled those actually existing when placing underwater concrete for the bottom of the dock. The concrete for these tests was deposited with tremies in water about 52 ft. deep. The blocks were about 4.5 ft. wide and 6.5 ft. long. The end of the tremie was held near one corner of the form so that concrete had to flow to an extreme distance of about 6 ft. after leaving the tremie. A 2-cu. yd. Ransome mixer was used for the concrete, which was made very wet, but with water limited so that it would not rise to the surface during transportation from mixer to tremie. The results from

eight of these large test blocks, and also from small cubes made from the same mixes which were seasoned in the laboratory, are given in Table 4.

The concrete in Block No. 2 was fairly smooth-flowing and plastic. The surface of the block when raised for examination was rough, but hard and compact.

The concrete in Block No. 9 was free-flowing, sticky, and generally excellent in appearance. When the block was removed from the water it was found that it had perfectly filled the form, and that the grain of the wood in the form was distinctly reproduced in the sides of the block; the top of the block was flat and nearly level. In short, this specimen was the equal of high-grade concrete placed under favorable conditions on shore. The concrete in this block weighed 151.2 lb. per cu. ft.

The concrete in Block No. 12 did not show any serious separation of materials, but it was not of uniform texture, and had not hardened satisfactorily after an immersion of 24 days. It weighed 147 lb. per cu. ft.

The concrete in Block No. 10 was very free-flowing and plastic, and presented a good appearance when raised for examination.

The concrete in Block No. 11 very much resembled that in Block No. 10, except that it was a little less plastic. It weighed 149.4 lb. per cu. ft.

The concrete in Block No. 3 was free-flowing and plastic, but it was found that there was considerable washed stone in the bottom of the form, which had accumulated during the early stage of the pouring, and that there were soft pockets in the block where the coral sand had segregated excessively.

The concrete in Block No. 8 was ashy in appearance, and was not plastic. The block was very inferior, and the ingredients were badly washed and separated.

The concrete in Block No. 13 was mixed moist, but not wet, with the result that the tremie choked repeatedly; the concrete did not flow smoothly to fill the form, and sea water entered, not only into the deposited mass, but also into the tremie; the result was failure, as far as obtaining a satisfactory concrete was concerned.

The mixture and method of placing the tremie concrete used in the coffer-dam surrounding Section II were the same as used for Block No. 9.

Tremies.—Approximately, 14 840 cu. yd. of concrete were deposited through tremies in water varying in depth from about 54 to 44 ft. A great deal of interesting experience in the use of tremies has been incidentally acquired, due to the fact that the product, which at first was practically worthless, was gradually improved until finally it attained a high degree of excellence. This improvement followed careful experiments with tremies of various diameters, manipulated in various ways, and handling concrete mixed in many different proportions with variously graded and selected materials. Tremies 12, 15, and 18 in. in diameter were used in these experiments, and the results seem to justify the following general conclusions:

(*a*).—The results from a tremie depend to a great extent on the proportions, character of materials, and plasticity of the concrete which is being used.

(*b*).—The excessive frictional resistance to the movement of concrete in a 12-in. pipe causes frequent clogging in the pipe and greatly reduces the pressure at the exit. Under these conditions, it becomes impracticable to hold the end of the tremie embedded in the deposited concrete, thereby bringing all newly placed concrete into direct contact with sea water, with consequent injury to the entire product.

(*c*).—The frictional resistance to the movement of concrete in an 18-in. pipe is not sufficient to prevent the occasional loss of a charge in the tremie, thereby interrupting the filling of a form, with the added uncertainty as to the quality of the product. There is no difficulty in maintaining the end of this tremie embedded in concrete, and readily filling the form without any disturbance of the mass which would admit sea water.

(*d*).—The frictional resistance in a 15-in. tremie is apparently just about right to obtain the proper discharge pressure necessary for efficiently regulating the flow of concrete by raising and lowering the tremie with the end maintained within the deposited mass. No difficulty is experienced, when using this tremie, due to short interruptions in the supply of concrete from the mixer. Concrete discharged from this

tremie flows freely to distant parts of the form, without causing disturbance in the mass which would admit sea water, and without any tendency for sea water to rise in the tremie.

(*e*).—A tremie 15 in. in diameter is best suited for the work, and was adopted and actually used for placing the greater part of the tremie concrete.

The 15-in. tremie consisted of a riveted steel pipe, with a funnel-shaped steel hopper, about 5 ft. in diameter, bolted to the upper end. The tremie hopper was suspended from a timber storage hopper having a capacity of about 2 cu. yd., and fitted with a 12-in. valve in the bottom for controlling the flow of concrete into the tremie. Concrete was mixed in a 2-cu. yd. mixer at the rate of from 40 to 50 batches per hour, each batch producing about 1.85 cu. yd. Concrete from the mixer was discharged into 2-cu. yd. bottom-dump tubs, which were transported on flat cars hauled by cable to a derrick, thence into the tremie storage hopper. When beginning operations, the tremie was set with its lower end resting on the bottom of the form and then raised from 2 to 3 in. A bag loosely filled with straw was then placed in the tremie hopper to serve as a piston which descended under the burden of concrete to force the sea water out of the tremie. It was customary to assemble about 6 cu. yd. of concrete at the derrick before starting to fill the tremie, as it was found that this quantity when rapidly poured was sufficient to charge the tremie fully and embed its end to a depth of from 1.5 to 3.0 ft., and effectually seal the tremie from the entrance of sea water.

Special effort was made, after the tremie was first properly charged, to supply the concrete required to fill the form quickly and regularly; by carefully manipulating the depth of the tremie to correspond with its supply of concrete, it was found that the surface of the concrete in the form could be maintained in an almost flat and level condition, with uniform displacement throughout the form, and with the exposure throughout the process of only one unvarying surface to the injurious effect of contact with sea water. The forms for tremie concrete were each about 12 ft. square, and were of rough 1-in. boards and 2 by 4-in. studding; after framing the pieces for one side of a form on the bank, it was sunk in a vertical position to its proper place; the sides of the form were then closely joined together and braced by a diver, who closed any openings in the bottom with concrete in bags and also made

sure that the form was properly cleared and ready for concrete just before pouring was begun. Approximately 40 cu. yd. of concrete were required to fill one form.

General Tests and Investigations.

Borings.—Numerous borings have been made at the dock site to determine sub-surface conditions. These consist of a series of 38 borings of the wash type which were made in 1908, before work on the dock was started, and a series of 18 of the core type made in 1913.

The preliminary borings were on the axial line of the dock, and on two parallel lines about 65 to 75 ft. on each side of the axis. The borings were at intervals of about 100 ft. on these lines, and were arranged so that there was one on each side line opposite one on the center line, to facilitate the making of cross-sections. The original ground level over the dock site varied between an elevation of 14 ft. above mean low-tide level to 8 ft. below. The preliminary borings were carried to about the same average depth of 75 ft. below tide level, or about 28 ft. below the bottom of the dock. The borings were made by driving a casing pipe into the ground, loosening the penetrated material by blasting and churning when necessary, and then removing the contents of the casing with a water jet from a small pipe within. The only samples of the underlying soil which could be obtained by this method were the deposits found in the bottom of a bucket in which the overflow from the casing was collected; due to the disintegration of the material and the removal of the lighter particles which this process involved, there was necessarily a considerable difference between the samples and the original formations which they represented.

There were several special reasons for undertaking the second series of borings made in 1913:

(*a*) To check the results found by the 1908 series.

(*b*) To find, if possible, an explanation for the peculiar movements of the coffer-dam on the three occasions when efforts were made to unwater the excavation.

(*c*) To determine more definitely the suitability of the site for the construction of a graving dock.

(*d*) To determine the weight of the materials in the various strata penetrated.

The new borings, therefore, were located near the points which had been selected for the preliminary borings, were carried to considerably greater depths than those reached by the earlier series, and were made by methods which permitted of obtaining much more accurate information regarding the materials penetrated.

The first fourteen borings of the 1913 series were made by using a 6-in. casing pipe in combination with the churning and jet devices which comprise the usual wash-boring outfit; a heavy driving rod fitted at the lower end with a short removable piece of 3-in. pipe or core barrel was utilized for obtaining samples. With this equipment it was found possible to drive the core barrel to undisturbed depths below the bottom of the casing, and obtain cores as frequently as desired, provided the material was of a nature or consistency which would remain in the core barrel while being raised. The core barrel was provided with holes above the highest point reached by the cores to prevent the forming of internal water pressure by an entering core which would tend to disintegrate or modify the character of the core when it was withdrawn. These fourteen borings ranged in depth from 84 to 192 ft., with an average of 144 ft. below low-tide level. It was found in practice that considerable force was frequently required to remove cores from the core barrel, and that probably the physical character, and especially the density, of the material was thereby affected.

The last four borings of the 1913 series were made with a rotary Calyx drilling outfit having dimensions for obtaining 2-in. cores. Cores obtained with this apparatus were not compressed or modified while being secured, and more truly represented the original formations than those obtained with the driving rod. These four borings reached depths varying from 94 to 107 ft., with an average depth of 99 ft. below low-tide level.

While certain borings were in progress, and when the top of the casing tube was only a short distance above sea level, it was noted that there was an overflow of fresh water from the casing; by increasing the elevation of the top of the casing it was found that the height to which the fresh water would rise could be computed by multiplying the depth of the water-bearing stratum by the ratio between the weights of salt and fresh water; in other words, the phenomenon was

not of Artesian origin, but indicated the presence of ground-water below an impervious stratum.

With due allowance for the very irregular character of the subsoil, the results from the 1913 series of borings were in close accord with those found from the preliminary borings in 1908. The mud stratum beneath the dock is apparently impervious and unbroken in its continuity, but varies in thickness from about 4 to 40 ft. The borings gave no evidence of unusual compressibility or of fluidity in any of the underlying formations.

The character of the mud stratum has been of vital importance throughout this work. The original design for the dock and the method selected by the contractor for its construction were undoubtedly based on the belief that the stratum was continuous, solid, impervious, and comparatively non-compressible. The stratum apparently has all these qualities in its original form, but it is probable that the conditions of solidity and imperviousness were impaired by building operations. In the writer's opinion, all the trouble which has been experienced since the work was started may be attributed to insufficient solidity of this stratum due to thin portions and to the breaking of the stratum by piling and by upheavals after removing the top cover. Figs. 8 and 9 are photographs of cores obtained from borings through the mud stratum; the plasticity of the material is indicated by the bands on the sample shown in Fig. 8, which formed when the core was driven out of the core barrel; Fig. 9 illustrates the tendency of the mud to check and crack when it dries. Samples of the mud when freshly obtained are plastic like putty or clay, but when immersed in water quickly and completely disintegrate like so much corn-meal. A sample placed on the tongue does not give any impression of grit. It is interesting to note that it is this material which forms the soil in which sugar cane thrives so wonderfully.

Bearing Tests.—Two tests were made to determine the bearing value of the soil in the bottom of the dry dock excavation. These tests were conducted before any piling had been driven for the support of the dock and after the excavation had been practically completed to the required depth at the points selected for the tests.

The first test, made in April, 1910, covered an area of 4 sq. ft. Under a load of 1.5 tons per sq. ft., there was a settlement of about 3 in. in 12 hours; the greater part of this settlement occurred immedi-

ately after the application of the load, as might have been expected with a load applied to soft ground. The load was then gradually increased, during a period of 25 min., until it amounted to 3 tons per sq. ft., under which the total settlement reached 5.25 in. after 29 hours, and was slowly increasing.

The second test was conducted in May, 1910, and was applied to a strongly trussed tripod having legs 10 ft. apart, each resting on a shoe having an area of 4 sq. ft. After 42 hours under a load of 1 ton per sq. ft., the settlements under each shoe were 2, $3\frac{3}{4}$, and $2\frac{1}{4}$ in., respectively. The load was gradually increased to 4 tons per sq. ft., which increased the settlements to $4\frac{1}{2}$, $9\frac{5}{8}$, and 5 in., respectively. After the load of 4 tons per sq. ft. had been supported for 24 hours, the settlements had increased to $4\frac{7}{8}$, $11\frac{1}{8}$, and $5\frac{3}{8}$ in.; after a further period of 17 hours under this load, the settlements had increased only $\frac{1}{100}$, $\frac{1}{100}$, and $\frac{1}{50}$ in., which are too small to be measured accurately with ordinary field instruments and for all practical purposes the tripod could be considered as having reached a condition of rest. The possible unequal distribution of the load to the three legs probably accounts in part for their unequal settlement, but the real cause of the inequality is undoubtedly due to a difference in the bearing value of the soil at the three points.

Pile Tests.—During May, 1911, five test piles were driven in the bottom of the coffer-dam surrounding Section I, and fifteen piles at various points in the bottom of the excavation outside of the coffer-dam. The penetration of the piles varied from 18.2 to 48.9 ft. After flooding the coffer-dam it was found that one of the test piles inside the coffer-dam had settled $\frac{3}{8}$ in., two had settled $\frac{1}{8}$ in., and one had remained without change; the record of the fifth pile has been lost. One of the piles inside the coffer-dam, with a penetration of 27.2 ft., was gradually loaded during a period of 3 hours with a load of 16 tons; the pile settled a total of $1\frac{5}{8}$ in. while being loaded, and, after carrying the load for 44 min., had gone down an additional $\frac{1}{8}$ in.; no more settlement had occurred 70 min. later.

Four tests were made during May, 1911, to determine the anchorage value or resistance to pulling of a single pile. The test piles had been driven in the bottom of the dock excavation, and were separated by considerable distances. It was found to be impracticable to apply

loads sufficient to draw the piles; the results of the tests are given in Table 5.

TABLE 5.—RESULTS OF TESTS IN PULLING PILES.

Pile No.	Penetration.	Pull.		Rise, in feet.	Permanent set.
		Tons.	Time, in hours.		
7	19.3 ft.	56	18	0.002	....
9	32.2 "	40	18	0.017	0.00
14	31.4 "	40	18	0.002	0.00
19	36.9 "	40	18	0.003	0.00

It is very probable that the "rise" of the piles under load was apparent rather than real, in view of the small movements noted and the complete recovery after removing the load, and were due either to observation errors or a slight straightening of the piles while under pull.

A test was made during February, 1913, to determine the pull which would be required to draw a pile from a block of concrete in which the head of the pile had been embedded. The pile was 45 ft. long, 12 in. in diameter at the butt, and 7.5 in. in diameter at the point. The pile was suspended in water with the butt pointing downward into a form resting on the bottom of the dock; concrete mixed in the proportions of 1:2:3.5 was poured into the form through a tremie until the head of the pile had been embedded to a depth of 5 ft. A direct and slowly increased pulling load was applied to the pile after the concrete had set for 31 days; when the pull amounted to 29.2 tons, the upper end of the pile broke off without any movement of the pile head having been noted; after getting a new hold on the pile the load was again gradually applied until it amounted to 47.0 tons, but without budging the pile head in the concrete.

During May and June, 1913, a loading test was made on a group of piles which had been driven in the bottom of the dock excavation. It had been planned to carry a grillage platform on four rows of five piles and apply the load on an upper deck above sea level, which was to be supported on the grillage by a braced trestle. Due to irregularities in spacing the piles in a depth of about 52 ft. of water, it was found possible to bring only fifteen of the piles to bear under the

grillage. The loading was begun on May 20th, and the load was gradually increased until May 31st, when it amounted to 400 tons; the load was allowed to remain until June 10th, and was then gradually removed during the next 4 days. The settlement slowly increased while supporting the fixed load, and amounted to 5.0, 1.1, 2.45, and 2.25 in., respectively, at the four corners of the platform at the time the unloading began. After the removal of the load there was a rise at the four corners of 3.25, 0.35, 1.25, and 1 in., respectively. After removing the trestle and grillage, it was found that the timber was badly crushed at various places, and there was evidence of deflection in the uprights; these conditions combined would probably account for a considerable part of the recorded settlements. This test applied an average load of about 26.7 tons to each of the fifteen piles, but, due to the crushing of the timber, there is much uncertainty as to the actual distribution of the load and the settlement of the piles under load. Observations on unloaded piles in the vicinity of the grillage showed settlements running up to 0.4 in., as the load was applied to the platform, but the latter was permanent after the removal of the load; these settlements would indicate a compression of the ground below the points of loaded piling.

During August and September, 1913, a second loading test was made on a group of twenty piles, in much the same manner as that followed during the preceding test, except that levels were taken on splines attached directly to the piles, and precautions were taken to eliminate errors which would result from the crushing or yielding of the temporary framework. Table 6 shows the results from this test. These results compare very closely with those obtained from the preceding test.

The specification for pile-driving provided for the use of a water jet, if directed by the officer in charge. In view of the impossibility of obtaining pile penetrations as great as were anticipated and as were desired for the adopted constructive methods, a special test was conducted during April, 1913, to determine the local practicability and value of the jet process. The test pile was 76 ft. long, 15 in. in diameter at the butt, and 9.5 in. in diameter at the point, and was driven approximately in the center of the dock excavation, in water 52 ft. deep. After 80 min. of jetting through a 2½-in. pipe, with a

⅞-in. nozzle, under a pressure varying from 150 to 350 lb. per sq. in., the pile had sunk 2.1 ft. The pile was then struck 35 blows with a 5-ton, 42-in. stroke, steam hammer, which added 4.3 ft. to the penetration. With difficulty the pile was then drawn and the jet was inserted in the hole and churned for 45 min., with water pressure at 350 lb., with the result that the hole was filled to a depth of 4.4 ft. with loosened coral rock which the jet could not remove. The jet was then taken out and the pile re-inserted and alternately driven, pulled, and re-driven, until it reached a penetration of 12 ft. The pile was then again pulled and inserted with the jet pipe, with the nozzle at the point of the pile; a jet was applied at 350 lb. pressure, and the pile came to rest at a penetration of 5.5 ft.; after continuing the jet for 15 min., with the weight of the hammer resting on the pile, the penetration had increased ½ ft. An effort was then made to drive the pile while the jet was in operation, with the nozzle held at the pile point, but after eight blows the nozzle became clogged and the jet was removed. The alternate driving and pulling of the pile was then resumed, with gains of about 12 in. in penetration for each twelve blows, until a total penetration of 14 ft. had been obtained, when further operations were suspended because of the great difficulties attending the pulling process.

Caisson, Pumps, and Capstans.

Only brief mention will be made of the caisson, pumping equipment, and electric capstans which, although necessary accessories, do not form part of the graving dock structure proper and are furnished under separate contracts.

The caisson is of the floating boat type, and is equipped with electrically operated valves, pumps, and capstans. Electricity for the operation of the caisson will be obtained through portable connections with the station service. The caisson, built and delivered by the Union Iron Works, of San Francisco, has cost $133 923.93, and, properly modified to suit different tidal conditions, is almost identical in design with the caissons provided for Dock No. 4 at New York and for Dock No. 2 at Puget Sound.

The pumping equipment comprises four main discharge pumps and two drainage pumps. All pumps are of the vertical-shaft, volute type, each operated by a direct-connected, 3-phase, 2 200-volt, induction motor. The main pumps operate at 219 to 222 rev. per min., have a 54-in. suction, 48-in. discharge, and deliver approximately 8 000 cu. ft. per min. against 32 ft. head; 10 600 cu. ft. at 20 ft. head; 11 600 cu. ft. at 10 ft. head; and 11 800 cu. ft at zero head; the approximate input into the motor corresponding with this service is 700 h.p. at 32 ft. head; 586 h.p. at 20 ft. head; 475 h.p. at 10 ft. head; and 360 h.p. at zero head; considering that a motor and pump, together with its suction and discharge friction, combine to form a unit, the efficiency of a unit based on this performance is approximately 71.4% at 32 ft. head, 70.2% at 20 ft. head, and 47.4% at 10 ft. head. The drainage pumps operate at 585 rev. per min., having 20-in. suction and discharge, and, when operating against a head varying from 37.5 to 42.5 ft., deliver approximately from 675 to 560 cu. ft. per min., with an input varying from 74.7 to 71.7 h.p., or with a combined efficiency varying from 66.3 to 64.4 per cent. The pumps are below the floor of the dock, thereby eliminating all priming troubles. The motors are on a floor above tide level. The weight of the rotor, shaft, and impeller, of the main pumps, is carried by a collar bearing, just below the motor. The journals, bearings, and steady rests required for the pumping equipment are lubricated by a continuous system, through which oil is circulated under a pressure of about 180

lb. per sq. in. The pumping equipment for the Pearl Harbor dock is practically identical with that which has been installed in connection with Dry Dock No. 4 at New York and Dry Dock No. 2 at Puget Sound, and the foregoing operating data are based on results actually obtained during the operation of those docks.

The dock is to be equipped with nine capstans, one at the head of the dock and four along each side. These capstans will be used for hauling a vessel into the dock and for locating and centering the vessel correctly with reference to the keel blocks which have been prepared for its support. Each capstan is operated by a 50-h.p., 220-volt, induction motor, and the apparatus is designed to give a rope pull of 35 000 lb. at the rate of 12 ft. per min., or of 14 000 lb. at the rate of 30 ft. per min. These capstans are identical with those at Dry Dock No. 4 at the Navy Yard, New York.

Suggested Plans.

The long series of troubles and difficulties which had marked the progress of field work, and which culminated in the collapse of the coffer-dam on February 17th, 1913, naturally led to serious thought being given to other methods of construction and changes in plans which would tend to avoid building hazards and insure successful results.

Cox Plan.—L. M. Cox, M. Am. Soc. C. E., Civil Engineer, U. S. N., suggested two different schemes for the work. The first was presented in 1911, and contemplated the adoption of a sectional method of construction in which the units would consist of boats or structures which would be partly constructed on shore and then floated to position and sunk in a manner very similar to that independently suggested at later dates by Mr. Harris and Mr. Noble.

Mr. Cox's second scheme, submitted during the early part of 1914, urged the practicability of constructing the dock by the general methods and according to the general plans which were being followed at the time of the collapse of the coffer-dam by utilizing a ballast tank to assist in resisting hydrostatic uplift on the bottom of the unwatered coffer-dam. The dimensions of the proposed tank were to be as great as practicable, within the limits of the clear space between the side-walls of the completed dock and the end bulkheads of the

coffer-dam. The tank was to have a substantial interior framework, designed to enable it to carry its full capacity of sea water when resting on a grillage support on the floor of the coffer-dam and at the same time to serve as part of the coffer-dam bracing. The primary function of the tank was to provide a ready means of applying a temporary ballast or loading to hold down the tremie-placed concrete bottom of the unwatered coffer-dam during the period required to complete the concrete work in the dock floor and side-walls. Work under the tank would be conducted in alleyways under the structure; these alleyways would first be arranged through the supporting grillage in which concrete would be placed to the required height and on which the tank would in turn be supported while the grillage was removed and concrete was placed in the vacated spaces. After the completion of the concrete work within any coffer-dam, the latter would be flooded and the tank emptied and floated through a gateway in the coffer-dam bulkhead and placed in readiness for use in the next adjacent coffer-dam.

Gayler Plan.—Recommendations for changes were submitted immediately after the collapse by E. R. Gayler, M. Am. Soc. C. E., Civil Engineer, U. S. N. This plan proposed to construct the dock of large concrete blocks joined together with tremie concrete and with steel reinforcement. Each block would weigh about 150 tons, and would be made on the surface of the ground in the vicinity of the dock. The plan had its inception in the fact that a floating crane having a capacity for handling loads of 150 gross tons had been provided as part of the station's equipment, and could be made serviceable for placing the blocks. Any upheaval of the dock during construction or after completion was to be avoided by increasing the thickness of the floor, thus not only adding to the strength of the floor, but incidentally making the weight of the dock greater than any possible hydrostatic uplift. All foundation piling would be carefully cut off, and the bottom would be prepared to the correct form before beginning to place the blocks. Spaces about 2 ft. wide would be left between adjacent blocks, except where longitudinal reinforcing trusses were to be placed, where the spaces would be about 6 ft. wide; these spaces would be filled later with tremie-placed concrete. Anchorages for transverse reinforcement would be provided in specially prepared

anchor-blocks; after placing the anchor-blocks the connecting steel would be laid in the open spaces between the blocks and in grooves formed in the intermediate blocks; each transverse chain or tie would include a turnbuckle which would be tightened by a diver before embedding it in the concrete. Unequal settlements and cracks after the completion of the dock would be prevented by first allowing each block to settle independently to a position of rest before bonding it with its adjacent blocks, then combining the blocks in the side-walls, to permit the independent adjustment of the walls as a whole to positions of rest, then bonding the floor blocks with each other and with the side-walls, with the adjustment of the transverse tension bars. Plate VI shows the general dimensions and arrangements proposed by this plan.

Harris Plan.—F. R. Harris, M. Am. Soc. C. E., Civil Engineer, U. S. N., submitted two plans in a letter dated September 26th, 1913. One plan was based on continuing the work in accordance with the plans and method which were being followed at the time of the collapse of the coffer-dam, but proposed to obtain stability while the coffer-dam was unwatered by increasing the quantity and distribution of the tremie-placed concrete in the seal of the coffer-dam.

Mr. Harris' second plan proposed the adoption of a sectional-boat method, like that suggested by Mr. Cox in 1911. Mr. Harris recommended that the length of the dock should be separated into ten portions, approximately 99 ft. long, measured longitudinally with the dock. The base or hull for each unit was to be made of 1:2:4 reinforced concrete, and was to be constructed on launching ways. The bottom of the base was to be flat, thus differing from the dish-shaped, dry dock bottom required by the original contract. The general dimensions for the base were: over-all depth, 15.5 ft.; bottom, 8 in. thick; sides, 8 in. thick at bottom, increasing uniformly to about 14 in. at top; ends, 10 in. thick; wales at ends and sides, about 22 in. wide and 18 in. deep; solid bulkheads, 14 in. thick, about 9.7 ft. from center to center, transverse to the dock; solid bulkheads, 10 in. thick, about 21 ft. from center to center, longitudinal to the dock; an intermediate triangular buttress between each two longitudinal bulkheads to stiffen and support the sides; all corners filleted. The base, after launching, would be fitted with timber walls and bracing to form a coffer-dam having sufficient height to reach above

tide level when the base was sunk to rest on the prepared bottom of the dock excavation. On the completion of the coffer-dam, the boat would be towed to place and gradually sunk to its final position as concrete was added to fill the bottom pockets and form the side-walls.

It was proposed to use very lean concrete, 1:3.5:7 mix, for filling the pockets in the boat and 1:3:6 concrete for the side-walls; this involved dependence on the impermeability of the thin walls and the bottom of the boat to exclude seepage and prevent the possible chemical disintegration of the lean concrete in the dock bottom, but made no provision for the safeguard of the comparatively lean concrete in the side-walls. Any unequal settlement of the ten sections, which would render the finished dock unsightly, would be corrected by placing a 6-in. layer of concrete over the entire dock floor shortly before the completion of the work, and making the total thickness of the floor 16 ft. A comparatively small quantity of transverse steel reinforcement would be embedded near the upper surface of the dock floor, to care for certain structural stresses. The spaces between adjacent sections would be sealed in the bottom by a small quantity of tremie-placed concrete which would tightly wedge between the slightly upward converging faces of the bases; concrete placed through a tremie or by other special method would be used for making the vertical seals between the side-walls.

Great care would undoubtedly be required in the execution of this plan, to prevent launching stresses, which would cause cracks or breaks in the thin walls and bottom of the bases, and to protect the sections against injury while in a floating condition, particularly when heavily loaded just before settling into position. Great care would also be necessary to have the bottom of the dock excavation perfectly prepared before placing the sections and to prevent earth from the side banks or other foreign matter from being deposited on the prepared bottom before settling a base. Any error in locating a section or serious accident to a partly completed section would be extremely costly and difficult to repair, as it would be impossible to raise a section after it had firmly settled on the bottom.

Noble Plans.—During the summer of 1913 the Secretary of the Navy retained the late Alfred Noble, Past-President, Am. Soc. C. E., as Consulting Engineer on Pearl Harbor Dry Dock matters. Mr. Noble

visited the site of the dock during August to make such personal inspections and investigations as he might desire, to supplement the voluminous records and data which had been furnished him, and on October 20th, 1913, submitted a comprehensive detailed report with his recommendations. The report emphasized the desirability of eliminating as far as possible all features of design and of construction which were experimental or hazardous, or which involved uncertainties as to the result, and urged that cost be subordinated to safety.

Mr. Noble suggested two general methods for continuing the work, which he designated as the "Type A" and "Type B" methods, either of which he thought might be advantageously adopted, but expressed a decided preference for "Type A". Both methods propose sections each about 100 ft. long, in the direction of the axis of the dock, and founded on a reinforced concrete base, built above the surface of the water and then floated and sunk in the desired position. The use of a floating dock in which to construct the bases was strongly recommended in preference to launching ways, in order to eliminate as far as possible any injury to the structures during the process of floating them, and to permit of correcting any defects in construction which might appear after immersion but before the actual removal of the bases from the floating dock.

The five-plane, dish-shaped form required by the original contract for the contour of the bottom surface of the dock prism is retained in both plans proposed by Mr. Noble, but the thickness of the dock floor at the center is increased from 16 to 18.5 ft., to eliminate or reduce the need of reinforcing metal for tensile stresses. The increase in the thickness of the floor would correspondingly increase the required excavation; that is a matter of moment, considering the fact that the dredging work would have to be conducted at such great depth below the water surface and that closely spaced piles have been driven over about four-fifths of the dock area, which would greatly complicate the difficulties attending dredging operations. It would probably be necessary to remove interfering pile heads by blasting, inasmuch as the points of cut-off are so deeply buried in the ground; the points of cut-off would necessarily be several inches below the finished bottom grade level to permit of the accurate surfacing of the bottom to receive the concrete bases. The final accurate grading of the bottom to the rather complicated form required for the support of the bases would constitute

one of the principal difficulties in the execution of these plans. Only a narrow space, 2 or 3 in. wide, would be left between adjacent sections, and the sealing of these spaces would involve little difficulty because of their narrow dimension. The very strong and stiff construction of the bases would enable them to be adjusted to considerable irregularities in the supporting value of the ground, without endangering their integrity.

The boat or base proposed for the "Type A" method would have a concrete bottom 2 ft. thick, walls 1.5 ft. thick, and 12-in. solid interior longitudinal and transverse bulkheads, about 14 ft. from center to center. All concrete would be heavily reinforced. The upper part of each base would be designed to receive a timber coffer-dam at each end, within which the side-walls for the dock would be constructed; provision would also be made for temporary sheeting and cribbing, which would be placed on top of the base between the end coffer-dam for use during the transporting and sinking of the base to position. A distinctive feature of this plan, and one which Mr. Noble considered very important, was the requirement that any base after leaving the floating dock should be quickly transported and sunk to position, thus reducing to a minimum the period during which a base was afloat and safeguarding that part of the work against accidents which might be very serious in their results. The rapid sinking of a base would be obtained by the admission of water into the coffer-dam. The open pockets formed by the interior bulkheads in the base would be filled with tremie-placed concrete, and the side-walls would be made of concrete placed under open and dry conditions within coffer-dams.

The essential difference between the "Type B" plan and that described for "Type A" is the method proposed for sinking the bases. In "Type B" the coffer-dam for each section would cover the entire area of the boat, and the boat would be sunk by the weight of the concrete filling, all of which would be placed under dry and open conditions. This plan is very similar to that suggested by Mr. Harris. Mr. Noble considered that the long period during which a base would be maintained in a floating condition while being filled with concrete introduced a building hazard of such serious nature as to render the adoption of the "Type B" method inadvisable. The ability to place nearly all concrete under favorable dry and open conditions, and the elimination from the boats of a considerable part of the longitudinal

reinforcing metal, which would have little value in the completed structure, are the principal advantages which were claimed for the "Type B" as compared with the "Type A" method.

Plate VI shows three progressive stages in the sinking of a boat and the building of a section of the dock, as proposed under both the "Type A" and the "Type B" methods.

Hollyday Plan.—On April 21st, 1914, R. C. Hollyday, M. Am. Soc. C. E., Civil Engineer, U. S. N., recommended the sectional boat method for the construction of the dock, in case it should be decided to depart from the original contract plans. Mr. Hollyday submitted outline details based on making each section or unit 50 ft. long, measured on the axis of the dock. The boat for each section would have a bottom of two layers of 12-in. square timbers bolted together, and fitted with detachable timber ends and side-walls; the ends and sides, designed for repeated use, would be extended upward to form the walls of a coffer-dam within which all concrete would be placed in the dry. The bottom of each section would be flat. The concrete floor of the dock would be 16 ft. thick, with steel reinforcement sufficient for all tensile stresses. The boat would be sunk to position as it was filled with concrete. The plan proposed to add considerable material to the concrete side-walls of the dock and to provide horizontal projecting shelves, 2 ft. wide, outside each side-wall at the elevation of the finished floor.

The Writer's Plans.—The addition of pig iron or metal scrap to concrete to increase the weight of the mass was recommended in July, 1913, to obviate the necessity for general changes in the plans in order to make the weight of the dock greater than any possible hydrostatic uplift and to hold the center line of pressures within the middle third of the concrete mass.

The substitution of steel plates and structural shapes for reinforced concrete was suggested in September, 1913, for use in making the boats or bases required for the sectional boat method of construction.

The method of construction and general plans subsequently adopted were submitted in April, 1914. These are described in detail later under the heading "Revised Plans".

Floating Type.—The desirability of providing a dry dock of the floating type, instead of the graving type, has been suggested. It is undoubtedly true that a dock of the floating type, having ample capacity, could be constructed in less time and at less cost than one of

the graving type; this statement is especially true for a dock at Pearl Harbor where the natural soil conditions render the deep excavation and sub-surface concrete work required for a graving dock both hazardous and very expensive. However, all questions as to the type of dock to be provided are in this case beyond discussion, inasmuch as the Congressional authorization for the work distinctly directs the construction of "one graving dry dock".

Revised Plans.

Revised plans for the dock, as shown in outline on Plate VII, were approved on November 19th, 1914, and its construction is now being energetically pushed in an effort to complete the work on or before June 30th, 1918.

General Details.—The dock will be built in sixteen sections, each covering the entire width and having a length in the direction of the dock axis of about 60 ft. The bottom of each section will be flat, and will consist of a structural steel frame embedded in concrete. The side-walls will be of concrete with a small quantity of vertical reinforcement near their outer faces. All concrete in each section will be placed under dry and open conditions favorable for performing concrete work, which will permit of continuous and thorough inspection. There will be a space between the bases of adjacent sections, diminishing from about 5 ft. wide at the bottom to 3 ft. wide at the top, which will be sealed in the bottom with concrete placed through a tremie; the upper part of the space between the bases will be filled with concrete placed in the dry after the dock is unwatered; the considerable distance between the bases is provided to facilitate the work of a diver in clearing the space before depositing the tremie concrete. The spaces between the side-walls of adjacent sections will be sealed with small coffer-dams, and the closure will be made with concrete placed under dry conditions after unwatering the dock. Reinforcing rods will be used to tie together the bases of the two outer sections.

The semicircular wall at the inner end of the dock will be made of large, pre-moulded, reinforced concrete, voussoir blocks in combination with concrete filling placed under dry and open conditions; a base similar in all respects to that used for the sections in the body of the dock will be used as a foundation for the end-wall; an accurately formed bed or seat will be prepared on the upper part of the base for the sup-

GENERAL PLAN

port of the wall; the voussoir blocks will weigh about 150 tons each, and will be made in forms on the bank adjacent to the excavation, within reach of the Station's large floating crane, which will be used in setting the blocks; a space about 4 ft. wide will be left between adjacent voussoirs, and this will be closed by an inner and an outer coffer-dam, after which the space will be unwatered and filled with concrete; a keyway or grouting space will be provided between the bottom of each block and its bed, which will be sealed when the concrete is placed in the open space adjoining the block.

Additional concrete will be placed under the side-walls, to make the bottom of the bases flat, and additional piles will be driven to support this concrete. The pump-well will be near the entrance, and will be integral with the side-wall of the dock. The pump-well will be founded on a steel boat supporting a timber coffer-dam; the boat will be sunk by the addition of the concrete required in the construction of the pump-well. The concrete will generally be made much richer than originally required.

Stress Analyses.—The structural details are based on numerous stress computations, which in turn are based on various assumptions, as follows:

That maximum tide will reach an elevation of 102.5, which is 2.5 ft. above mean low tide and 1.3 ft. above mean high tide.

That sea water weighs 64 lb. per cu. ft.

That effective hydrostatic pressure on the bottom of the dock will equal full sea pressure at that depth, due to the extremely porous character of the soil.

That the earth side-banks of the excavation for the dock will take a natural slope of 1:1 both above and below tide level.

That the soil above extreme high tide level at Elevation 102.5 weighs 102 lb. per cu. ft., and that its submerged weight is 63 lb. per cu. ft. below this level. The equivalent liquid pressures on a vertical surface are 17.5 and 10.8 lb. per sq. ft., respectively.

That concrete weighs 150 lb. per cu. ft.

That there are transverse steel trusses embedded in the concrete bottom of the dock which provide the equivalent, per linear foot of dock, of 3 sq. in. of metal in the top chord and 1.6 sq. in. in the bottom chord.

That there is water pressure, but no earth pressure, on those portions of the upper horizontal surface of the base which project beyond the outer vertical faces of the side-walls.

That there is no Artesian pressure which would affect the hydrostatic pressure on the bottom of the dock.

On the foregoing assumptions, the dock was analyzed to determine the stresses which would result within its structure, depending on varying external forces and the manipulation of the dock. The stress diagrams on Plates VIII and IX have been made for the following cases:

Case A.—Uniform soil and water pressure under the bottom of the dock; dock empty; external water and earth pressure on side-walls.

Case B.—Uniform soil and water pressure under the bottom of the dock; dock empty; external water pressure only on side-walls.

Case C.—Uniform soil pressure under the bottom of the dock; dock full of water; external earth pressure on side-walls.

Case D.—Uniform soil pressure under the bottom of the dock; dock full of water; external water pressure only on side-walls.

Case E.—Uniform soil and water pressure under the bottom of the dock; ship load of 200 000 lb. per lin. ft. of dock, 120 000 lb. on keel block, and 40 000 lb. on each side-block; external water and earth pressure on side-walls.

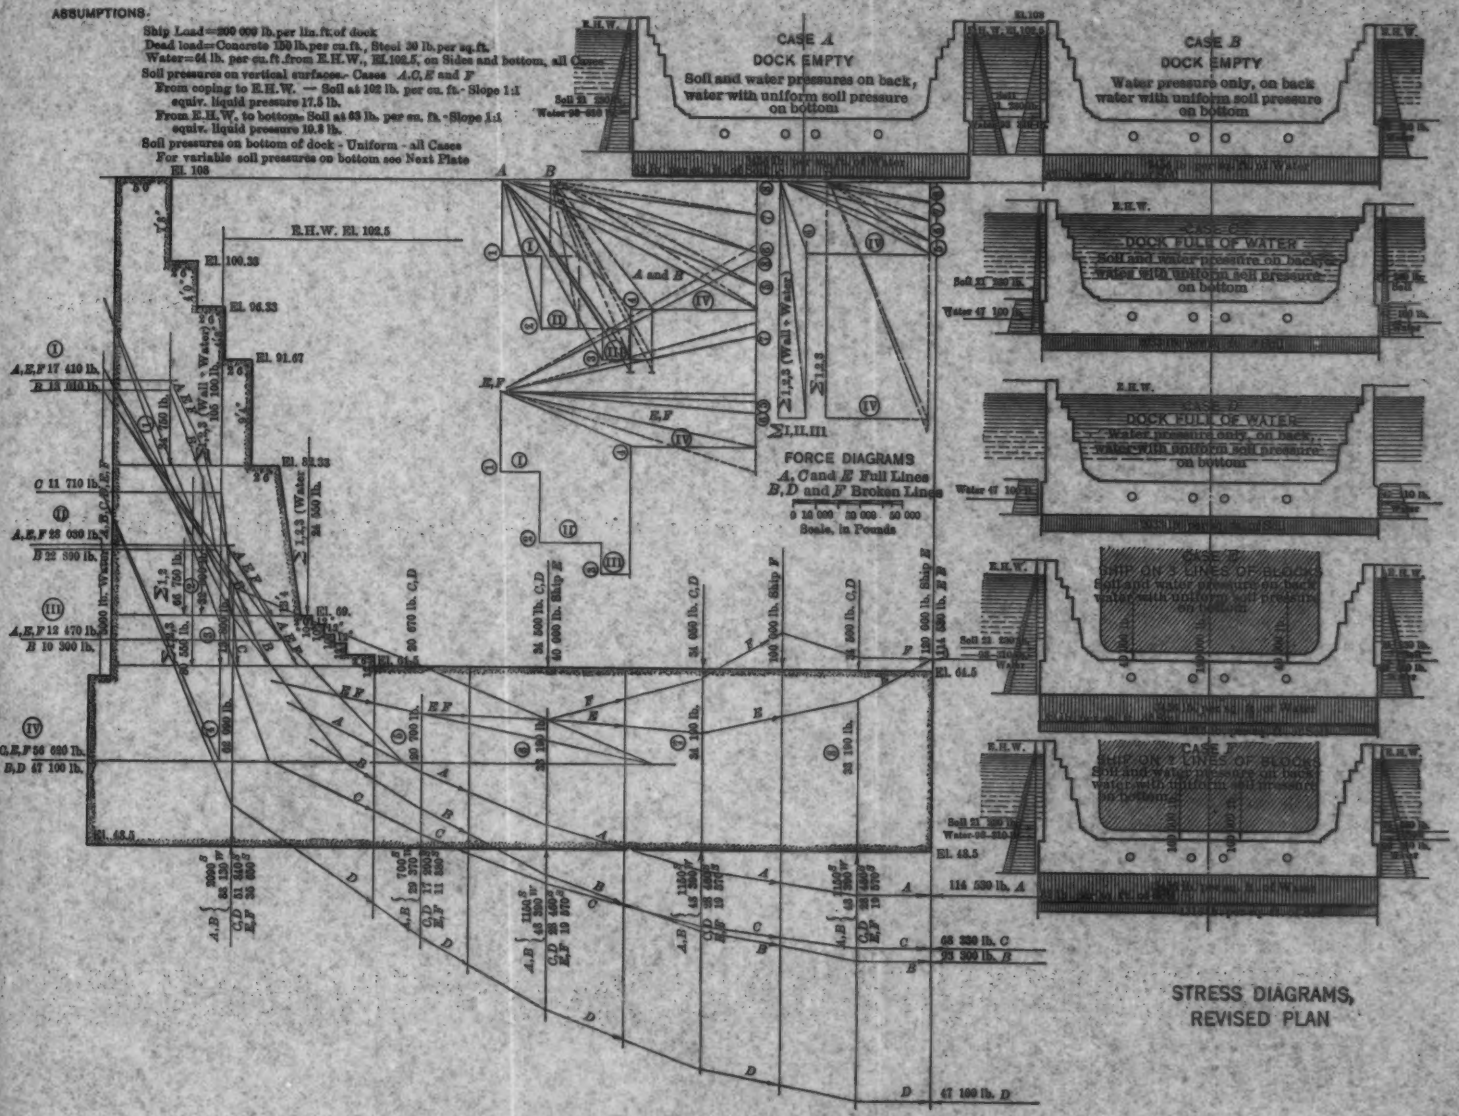
Case F.—Uniform soil and water pressure under the bottom of the dock; ship load of 200 000 lb. per lin. ft. of dock, one-half on each side-block; external water and earth pressure on side-walls.

Case G.—Intensity of soil pressure under the dock varies with the superimposed load and strain of dock; dock empty; external water and earth pressure on side-walls.

Case H.—Intensity of soil pressure under the dock varies with the superimposed load and strain of dock; dock empty; external water pressure only on side-walls.

Case I.—Intensity of soil pressure under the dock varies with the superimposed load and strain of dock; dock full of water; external water and earth pressure on side-walls.

Case J.—Intensity of soil pressure under the dock varies with the superimposed load and strain of dock; dock full of water; external water pressure only on side-walls.



ASSUMPTIONS.
Ship Load=800 000 lb. per lin. ft. of dock
Dead load=Concrete 150 lb. per cu. ft., Steel 30 lb. per sq. ft.
Water=64 lb. per cu. ft. from E.H.W., El. 102.5, on Sides and bottom, all Cases

STRESS DIAGRAMS,
REVISED PLAN

Case K.—Intensity of soil pressure under the dock varies with the superimposed load and strain of dock; ship load of 200 000 lb. per lin. ft. of dock, 120 000 lb. on keel block, and 40 000 lb. on each side-block; water and earth pressure on side-walls.

Case L.—Intensity of soil pressure under the dock varies with the superimposed load and strain of dock; ship load of 200 000 lb. per lin. ft. of dock, one-half on each side-block; external water and earth pressure on side-walls.

The load per square foot on the soil underlying the dock is: for Case *A*, 82 lb.; Case *B*, 82 lb.; Case *C*, 2 033 lb.; Case *D*, 2 033 lb.; Case *E*, 1 398 lb.; Case *F*, 1 398 lb.; Case *G*, 82 lb. under the sides, increasing to 217 lb. at a distance of 50.5 ft. from the center, then decreasing to zero at a point 28 ft. from the center; Case *H*, same as Case *G;* Case *I*, 2 350 lb. under the sides and to a point 50.5 ft. from the center, then uniformly decreasing to 1 395 lb. at the center; Case *J*, same as Case *I;* Case *K*, 82 lb. at the sides, increasing uniformly to 2 007 lb. at a point 28 ft. from the center, then uniform to the center; Case *L*, 82 lb. under the sides, increasing uniformly to 2 304 lb. at a point 14 ft. from the center, then uniform to the center.

The pressure on the soil is so small when the dock is empty, as treated in Cases *A* and *B*—only 82 lb. per sq. ft.—that it seems improbable that there will be any great variation in the intensity of the pressure. Assuming, however, that there will be a variation, as given under Cases *G* and *H*, there would be a reduction in the bending moment at the center of the dock, which, in comparing Case *G* with Case *A*, would reduce the stresses in the steel and concrete from 15 430 and 472 lb. per sq. in., respectively, to 12 150 and 412 lb.; and, comparing Case *H* with Case *B*, would reduce the unit stress from 25 330 and 592 lb. to 23 260 and 558 lb. These latter stresses, as computed for Cases *B* and *H*, cannot actually occur, as the specification governing the work requires that the back-filling outside the side-walls of the dock shall be placed before the dock is emptied.

The slight variation in soil pressure beneath the dock, computed for Cases *I* and *J*, as compared with the condition of uniform pressure computed for Cases *C* and *D*, results in reducing the bending moment at the center of the dock. Comparing Case *I* with Case *C:* this reduces the unit stresses in the steel and concrete from 17 300 and 413 lb. to 5 480 and 213 lb. Comparing Case *J* with Case *D:* the unit stresses

in the steel and concrete are reduced from 28 350 and 535 lb. to 15 080 and 334 lb. The unit stresses would be still further reduced with further small variations in the intensity of the supporting soil pressure. Inasmuch as a considerable deformation or strain of the dry dock structure would necessarily have to occur before destructive unit stresses could be developed, and as these changes would assuredly introduce variations in the intensity of the soil pressure, with reductions in stresses even greater than those previously computed, it may be concluded that the dock as designed will be safe when filled with water.

Slight variations in the intensity of the soil pressure beneath the dock, to conform with the variations in the superimposed load when the dock is pumped out and carries a ship on the blocks, result in comparatively large changes in the unit stresses in the dock structure. Assuming variations in the soil pressures, which would logically follow from the more or less elastic nature of the dock structure when under strain, and with variations confined within the narrow limits computed for Cases *K* and *L*, as compared with the uniform pressures computed for Cases *E* and *F*, shows that the unit stress in the steel in the bottom chord would be reduced from 14 140 lb. tension in Case *E* to 750 lb. compression for Case *K*, with corresponding reduction in the unit compression in the concrete from 386 to 50 lb.; comparing Case *L* with Case *F*, the unit stress in the bottom chord steel is changed from 14 140 lb. tension to 116 lb. compression, and the unit compression in the concrete is reduced from 386 to 80 lb. From these figures it is concluded that the dock can safely carry the assumed ship loading.

It is apparent from the foregoing analysis that the critical condition of loading is that shown by the stress diagram, *A*, which assumes the dock to be empty, with hydrostatic and earth pressures on the side-walls. Slight variations in the intensity of the soil pressure beneath the dock, for this condition, will have very little effect on the unit stresses in the dock structure. The center line of pressure within the bottom of the dock prism may be moved farther into the body of concrete by assuming an induced passive soil pressure or greater active soil pressure on the side-walls, but this would bring the center line of pressure dangerously near the haunch or toe of the side-walls; vertical reinforcement in each side-wall, equivalent to 0.9 sq. in. of steel per lin. ft. of dock, has been provided to meet this contingency.

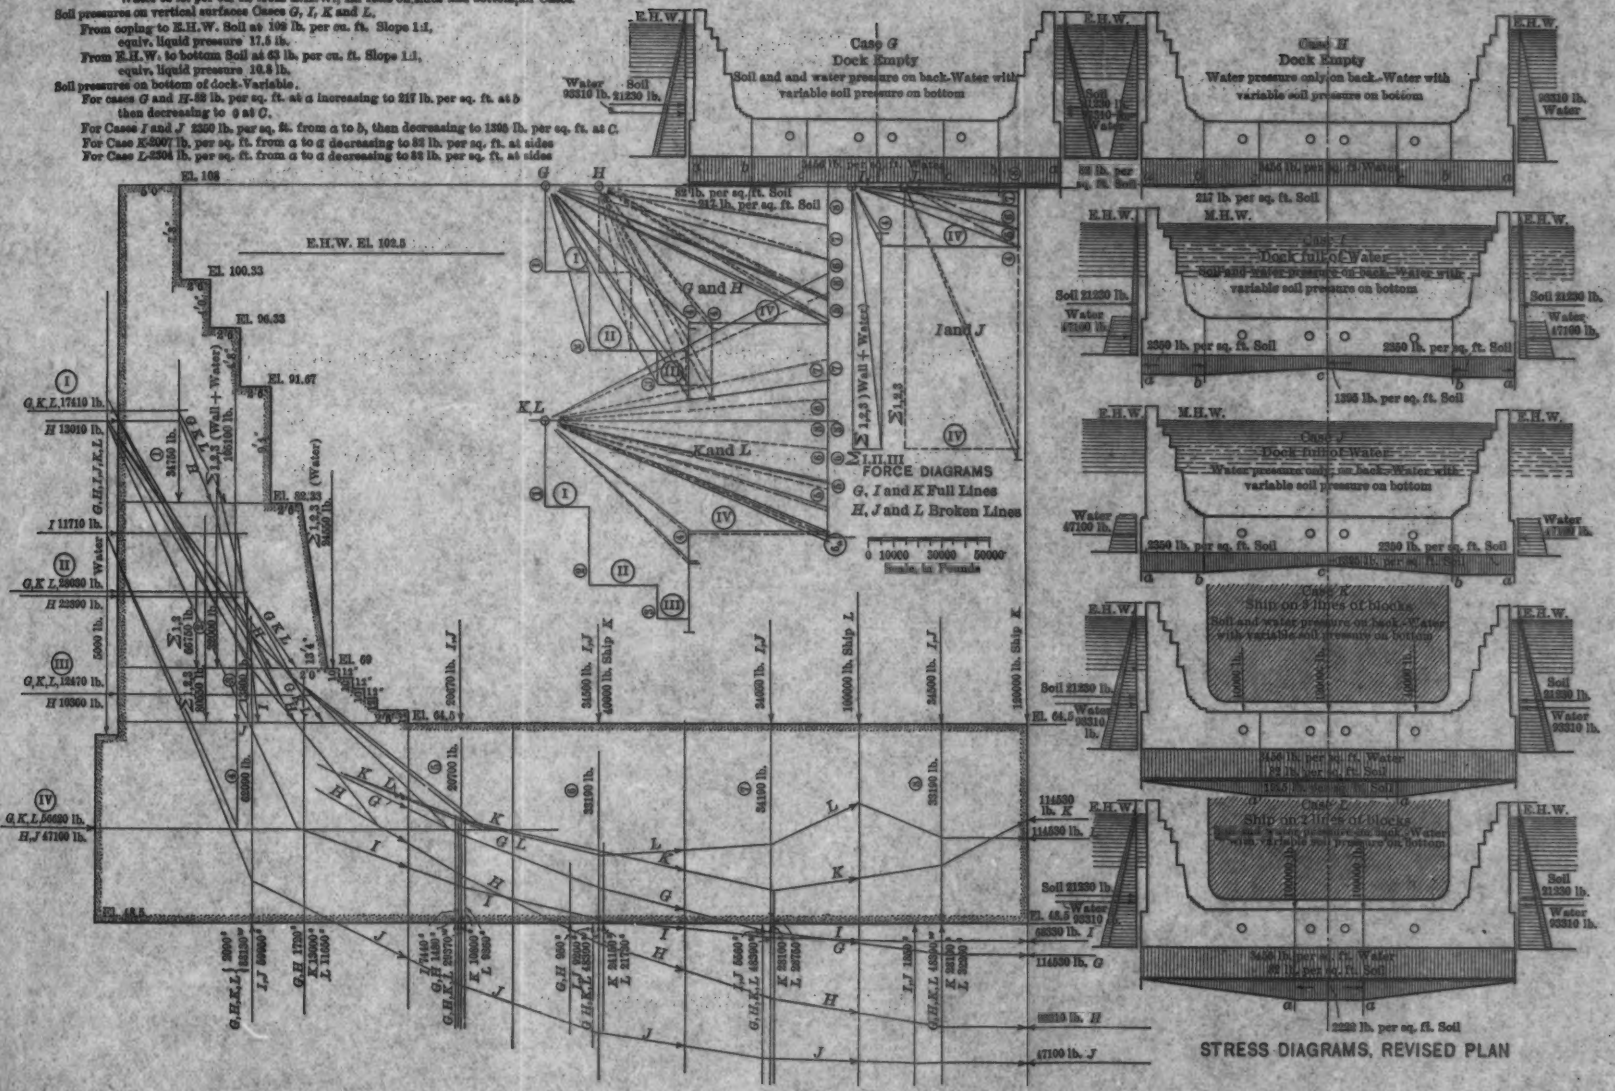
STANFORD ON
PEARL HARBOR DRY DOCK.

ASSUMPTIONS: Ship load = 250 000 lb. per lin. ft. of Dock
Dead load = Concrete 150 lb. per cu. ft., Steel 30 lb. per sq. ft. bottom.
Water 64 lb. per cu. ft. from E.H.W., El. 102.5 on sides and bottom, all Cases.
Soil pressures on vertical surfaces Cases *G*, *I*, *K* and *L*.
From coping to E.H.W. Soil at 106 lb. per cu. ft. Slope 1:1, equiv. liquid pressure 17.5 lb.
From E.H.W. to bottom Soil at 63 lb. per cu. ft. Slope 1:1, equiv. liquid pressure 10.5 lb.
Soil pressures on bottom of dock-Variable.
For cases *G* and *H*-82 lb. per sq. ft. at *a* increasing to 217 lb. per sq. ft. at *b* then decreasing to 0 at *C*.
For Cases *I* and *J* 2350 lb. per sq. ft. from *a* to *b*, then decreasing to 1395 lb. per sq. ft. at *C*.
For Case *K*-2007 lb. per sq. ft. from *a* to *d* decreasing to 82 lb. per sq. ft. at sides
For Case *L*-2504 lb. per sq. ft. from *a* to *d* decreasing to 82 lb. per sq. ft. at sides



STRESS DIAGRAMS, REVISED PLAN

The weight of the dock is 12 480 lb. per lin. ft. of dock in excess of the hydrostatic pressure on the bottom.

The safety and sufficiency of the dock structure are further insured by various forces which have not been evaluated in the foregoing treatment, but which have material magnitude and will be positive and reliable in their action. These additional elements of strength are in the nature of factors of safety, and include the following items:

(*a*).—The pile-supported concrete prism, which surrounds the dock to carry the outer rail of the crane track, is secured to the side-walls of the dock near the coping level by closely placed reinforced concrete ties, and serves to anchor or support the side-walls against inward movement.

(*b*).—The "plums" or "one-man stone", which will be embedded in the concrete, weigh from 167 to 173 lb. per cu. ft. The unit weight of 150 lb. assumed for concrete in making the stress diagrams was not increased on account of these "plums". The specifications provide that as large a percentage of plums may be used as may be consistent with the obtaining of strong, dense, and impervious concrete. The addition of plums will undoubtedly add quite a little to the assumed average unit weight of the mass concrete.

(*c*).—It has just been shown that the critical loading condition for the dock is that discussed under Case *A*, which assumes the dock to be empty. Under this loading condition, the weight of the blocking equipment which will be secured to the floor of the dock will be directly effective, and will reduce materially the unit stresses in the dock floor.

(*d*).—The weight of the soil on the shelves which project beyond the outer faces of the side-walls will add to the weight of the dock to resist flotation in the structure.

Special Plant.—The contractors are providing two special items of plant which are necessary for carrying on the work. These consist of a floating dry dock and a steel structure which, for want of a better name, will be called a coffer-dam-boat.

The floating dock is being made of timber, and will have a lifting capacity of about 3 500 tons. The general dimensions of the dock are: over-all width, 100 ft.; clear width between side-walls, 76 ft.; depth of bottom pontoons below floor, 12 ft.; over-all length, 214 ft.; height of side-walls above floor of dock, 34 ft.; top width of side-walls, 8 ft.;

length of side-walls, 164 ft. The bottom is divided into five pontoons, each 32 ft. wide, with a space 12 in. wide between adjacent pontoons. There is an outrigger, 25 ft. long, at each end of the dock. Each pontoon has a small side-wall, 4 ft. high and 12 ft. wide, at each end, to which the main side-walls of the dock are secured. The maximum draft of the floating dock is 41.5 ft., and will occur when the dock is lowered to receive the coffer-dam-boat; the top of the floating dock will be 4.5 ft. above the water surface in this position. There is a bracket on the inner face and near the top of each side-wall which will be loaded with about 100 tons of ballast to relieve the bending moment in the pontoons under certain conditions of loading.

The coffer-dam-boat is a structure which fulfills several requirements; it is a true coffer-dam, as it will exclude water from a working space which is open to the atmosphere and is below sea level; it is a boat, because it will be used for transporting and for containing a load, and because it can be alternately sunk and floated. Its service as a boat will be actually required to transport the partly completed bases for the sections of the concrete dock and to contain water which will be used to increase its weight; it will be repeatedly sunk, to locate the bases on the bottom and to impose its loaded weight as ballast on the bases to resist hydrostatic uplift; it will be repeatedly floated, to clear the completed dock sections of falsework and for repeated use in handling the bases on which the sections are founded. The structure will be entirely of steel, with the exception of a small quantity of removable timber bracing in the end pontoons, and may be described as an open boat, 108 ft. long, 60 ft. wide, and 38.5 ft. deep, with sides extended longitudinally and downward to form a U-shaped coffer-dam which will surround the ends and bottom of the boat. The coffer-dam space at each end of the boat is 22 ft. wide, and is 6 ft. 3§ in. high under the boat. There is permanent steel bracing, together with removable timber bracing, in each vertical leg of the coffer-dam. Numerous braced steel stools are connected to the bottom of the boat, for use while transporting a base and to support the weight on the bottom when the boat is sunk and resting on a base frame. The interior space in the boat is sub-divided into four equal water-tight compartments by a transverse and a longitudinal bulkhead; these compartments are fitted with pumps, piping, and valves for use in adjusting the trim of the boat; the bulkheads are not heavily braced or stiffened, as only a

small difference in level of the water in the four compartments is anticipated. Figs. 13 and 14 are photographs of a model showing the general form and construction of the coffer-dam-boat and giving some idea of the heavy framing and bracing required. The estimated weight of the structure is 875 tons.

Field Work.—A sufficient area underlying the dock will first be cleared of all earth, débris, and pile heads to a level sub-grade 12 in. below the finished grade. Shortly before placing the base for any section of the dock, the area which is to be covered will be swept by a frame having its lower edge held at a level 6 in. below the finished grade, to be sure that all projecting points have been removed, after which the area will be carefully brought to the required grade with broken stone and sand filling.

All piles which have been driven and were injured by the previous upheaval, or which will be too short to be reliable after the excavation is deepened, will be replaced with suitable piling. The additional piling required for the supports of the heavier dock will also be driven.

The structural steel frame required for the base of each section will weigh about 153 tons. This steelwork is being fabricated at Ambridge, Pa., in accordance with the standard specifications for material and workmanship contained in the 1914 handbook of the United States Steel Products Company for steelwork for buildings, using steel covered by Classes "B" and "C". Fig. 10 is a photograph of a model of the steel frame for one of the bases, and Fig. 11 shows the base as it will appear when erected on the floor of a floating dry dock. It may be noted that the model of the floating dock shown on Fig. 11 and on any subsequent illustrations is that of an assumed dock, and does not represent the one now under construction and previously described.

The steel frame comprises seven trusses, 152 ft. long, and 10 ft. from center to center; the trusses will be in a direction transverse to the axis of the dock when in position. Each truss has twelve panels and is 14.75 ft. deep over all. Adjacent trusses will be connected by cross-bracing at each panel point. The top chords of the interior trusses in the frame at the center panels are composed of two 6 by 6 by $\frac{5}{8}$-in. angles, one 20 by $\frac{1}{2}$-in. plate, and two $14\frac{1}{2}$ by $\frac{3}{8}$-in. side-plates; the lower chords of the interior trusses are composed of two 6 by 4 by $\frac{9}{16}$-in. angles and one $14\frac{1}{2}$ by $\frac{3}{8}$-in. plate. The intermediate posts in the interior trusses are composed of four 6 by 4 by $\frac{9}{16}$-in. angles and one

12 by ½-in. plate, and are very heavy, in order to carry the water load of the boat when the base is first settled into position. The exterior trusses of each frame and the end bracing connecting the seven trusses in a frame have no diagonal web members; the top chords are made of a 15-in. 33-lb. channel, with the web horizontal, in combination with a vertical 30 by $\frac{5}{16}$-in. web-plate, which is stiffened near the lower edge with a 3 by 3 by $\frac{5}{16}$-in. angle; the angles in the lower chords have their vertical legs turned down, in order that the outstanding legs will be more effectively protected by the concrete matrix in which the frame is to be embedded. The steel frames will be erected, aligned, and riveted on the floor of the floating dock.

The concrete work may be separated into two principal classes; the first will include practically all concrete which is placed under dry and favorable conditions, and the second will include that placed under water through a tremie. About 133 700 cu. yd. of concrete will be placed under dry conditions, including the massive work in the body of the dock, in the pump-well, and in the portions of the quay walls adjacent to the dock entrance; this concrete will be mixed in the proportion of 100 lb. of cement, ¾ cu. ft. of coral sand, 1½ cu. ft. of crusher screenings, and 4 cu. ft. of broken stone; "plums" or large pieces of rock may be embedded in the concrete in quantity which will be consistent with obtaining satisfactorily dense, strong, and impervious concrete. About 6 500 cu. yd. of concrete will be placed under water through a tremie, which includes about 2 500 cu. yd. for making the seals between the bases of adjacent sections and under the voussoirs at the head of the dock and 4 000 cu. yd. in the pump-well; this concrete will be mixed in the proportion of 100 lb. of cement, ⅔ cu. ft. of coast sand, 1⅓ cu. ft. of crusher screenings, and 3½ cu. ft. of broken stone. The exposed faces of the side-walls and the wearing surface of the floor of the dock, also the interior walls and floors of the pump-well and connected culverts, will be finished with a coating of "lavalithic", which will be placed at the same time as the concrete backing; the "lavalithic" will be mixed in the proportion of 100 lb. of cement, ½ cu. ft. of coast sand, and 1½ cu. ft. of crusher screenings; and the coating will be from 1½ to 2 in. thick.

Work will be started placing the concrete to embed a steel base frame just as soon as the erection of the steel frame is completed. A layer of thin boards or other suitable material will be placed on the

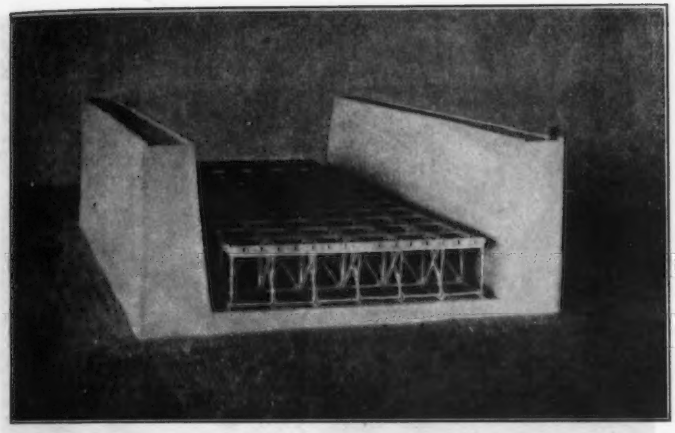


FIG. 11.—STEEL FRAME FOR BASE OF SECTION ERECTED ON FLOATING DOCK.

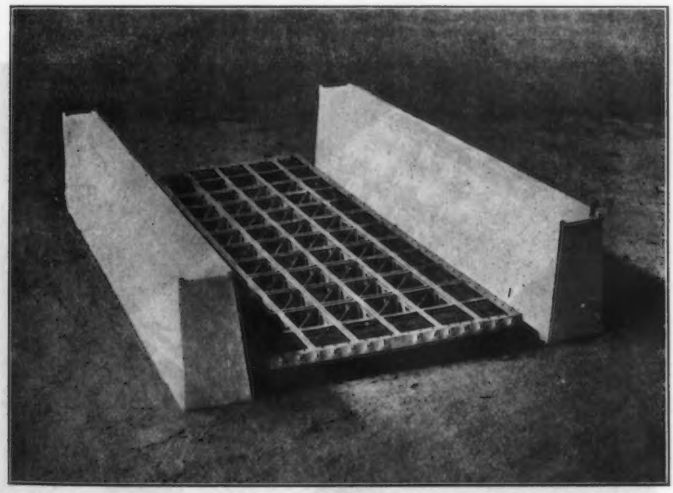

FIG. 12.—STEEL FRAME WITH EMBEDDING CONCRETE PARTLY PLACED.
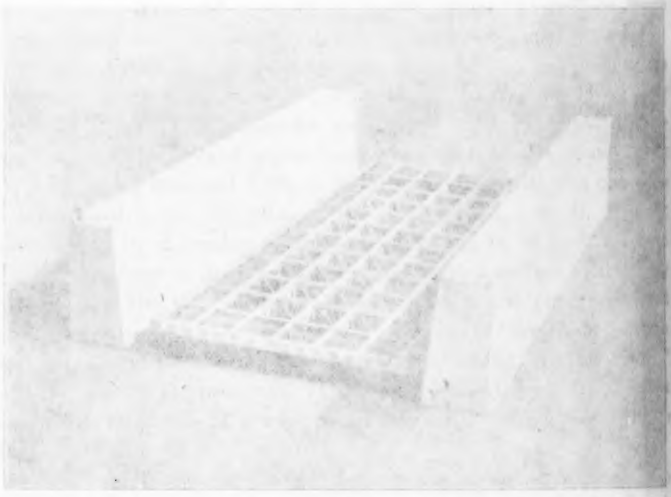
(At this stage the partly completed base is ready to be removed from the floating dock.)



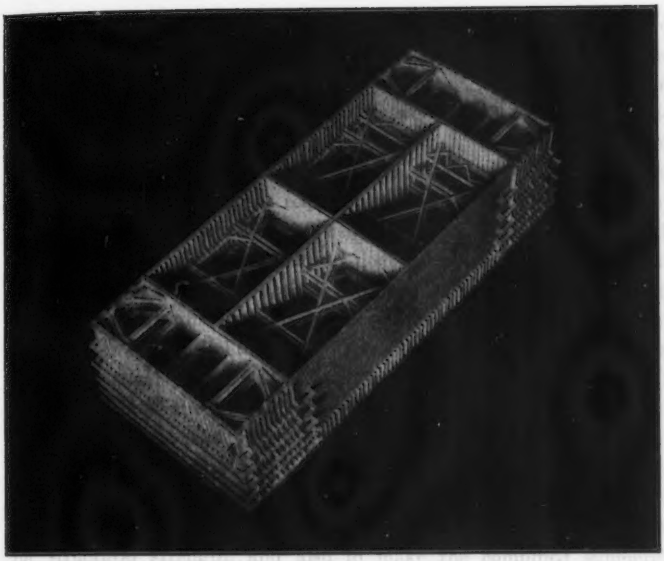


FIG. 13.—TOP VIEW OF COFFER-DAM-BOAT USED FOR TRANSPORTING AND SINKING SECTION BASES, AND REQUIRED FOR THE COMPLETION OF EACH SECTION.

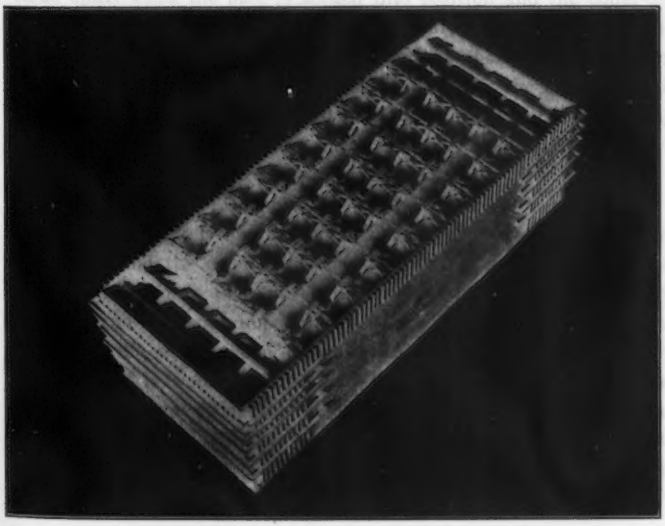

FIG. 14.—BOTTOM VIEW OF COFFER-DAM-BOAT USED FOR TRANSPORTING AND SINKING SECTION BASES, AND REQUIRED FOR THE COMPLETION OF EACH SECTION.

FIG. 13.—TOP VIEW OF COPPER-DAM-BOAT USED FOR TRANSPORTING AND SINKING SECTION BARGE, AND REQUIRED FOR THE COMPLETION OF EACH SECTION.

FIG. 14.—BOTTOM VIEW OF COPPER DAM-BOAT USED FOR TRANSPORTING AND SINKING SECTION BARGE, AND REQUIRED FOR THE COMPLETION OF EACH SECTION.

floor of the floating dock before the steel frame is erected and on which the concrete will be placed; this loose covering will protect the dock floor from injury when the concrete is placed, and will tend to prevent the suction or adhesion between the base and the floor of the floating dock when the base is removed. The steel frame and side-walls of the floating dock will provide ready means for securing and shoring the form work required to confine the concrete. About 3 500 cu. yd. of concrete will be placed for each base while the structure is carried on the floating dock; this concrete will be about 8 ft. thick over the entire area of the base, and will be banked solidly around the side-walls and ends to the extreme top of the steel frame; care will be taken to obtain a tight seal between the banked concrete and the vertical 30-in. plate which forms part of the top chord of the side girders and end bracing of the steel frame; the thickness of the concrete banks will be made ample to prevent any inward movement of the sides and ends of the base when subjected to the pressures which will occur during the later stages of the work; the depth of 8 ft. of concrete in the bottom of the base is required for structural strength, and also to make the combined submerged weight of the base and coffer-dam-boat sufficient to resist the hydrostatic uplift when the base is settled into position and the coffer-dam unwatered. The estimated weight of the partly completed base when ready to be removed from the floating dock is about 7 250 short tons; the estimated displacement of the base, assuming the dished interior to be free of water, is about 4 320 short tons. Fig. 12 is a photograph showing the appearance of a partly embedded steel frame resting on the floating dock and ready to be removed.

After completing that portion of the work on a base which is performed while it is on the floor of the floating dock, the dock will be lowered and the coffer-dam-boat floated to position over the base. The floating dock is then raised until it has lifted the joint between the base and the superimposed coffer-dam-boat to a level above the surface of the water, when the joint will be made with bolts, using a lead gasket between the top flange of the base and the lower flange of the coffer-dam to obtain water-tightness. The stools under the bottom of the boat will bear over panel points of the trusses in the steel frame when the coffer-dam-boat and base are connected, and the stools and frame will be connected with bolts.

The top chords of the outside trusses and end girders of the steel frames are fitted with exterior shelf-angles forming pockets to receive the lower ends of bolts which will be used to bond together the coffer-dam-boat and bases; these bolts will be long enough to reach the top of the coffer-dam to facilitate their detachment after completing a section of the dock without requiring the services of a diver. The bolts connecting the stools combined with the exterior bolts will have ample strength to carry the weight of a suspended base. Fig. 15 shows the coffer-dam-boat in position over a base with the floating dock raised to bring the joint between the coffer-dam and the base above the surface of the water. Fig. 16 shows the floating dock lowered sufficiently to float the coffer-dam-boat with its suspended base or load which is ready to be transported to the desired location over the dock site. All the water entering the partly completed dish-shaped base when the floating dock is lowered to receive the coffer-dam-boat will be pumped out after the joint between the coffer-dam and base has been completed, and as this space will then be fully protected against the entrance of water, by the walls of the coffer-dam with its temporary concrete steel bottom, there should be no difficulty in keeping the space dry during the transportation and sinking of the base and while the concrete is being placed to complete the dock section of which the base will form a part.

When the coffer-dam-boat with suspended base has been floated to the desired location, the boat will be sunk by admitting water into its interior compartments until the base comes to rest on the bottom of the dock excavation. The rate of sinking and trim of the boat will be under perfect control during the entire sinking process, and, by regulating the quantity of water in the boat, the base could readily be raised and again sunk if it should be desired to clear the bottom or to obtain a better location. After the base has been satisfactorily placed, it will be firmly held in position by the weight of the coffer-dam-boat aided by the weight of the water in the boat. Fig. 17 shows the coffer-dam-boat resting over a base which has been placed; the boat is full of water but the space within the coffer-dam is dry. The concrete required to complete the section to a point above high-tide level will then be placed in the dry space within the coffer-dam; the temporary bracing in the ends of the coffer-dam will be modified as required for the construction of the side-walls. The

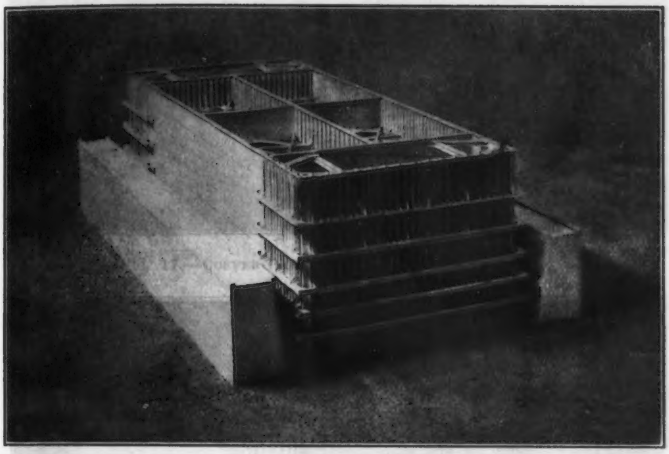

FIG. 15.—COFFER-DAM-BOAT MOUNTED ON SECTION BASE, READY FOR SINKING THE FLOATING DOCK.

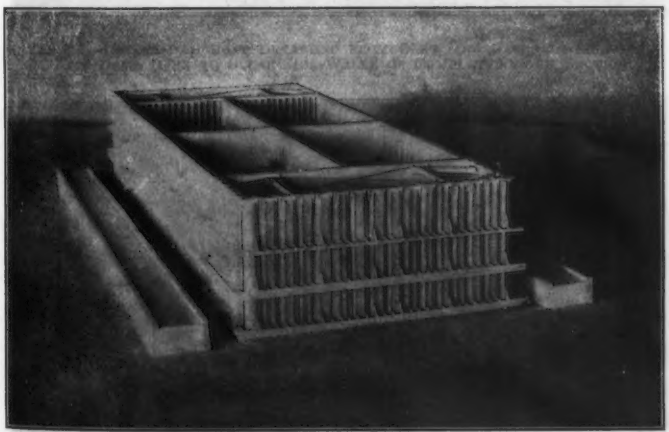

FIG. 16.—FLOATING DOCK IN DEEPEST POSITION, JUST PREVIOUS TO REMOVAL OF COFFER-DAM-BOAT WITH ITS ATTACHED BASE.

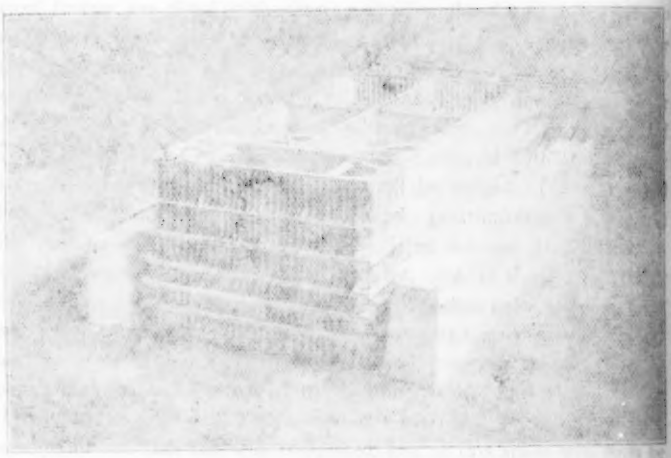

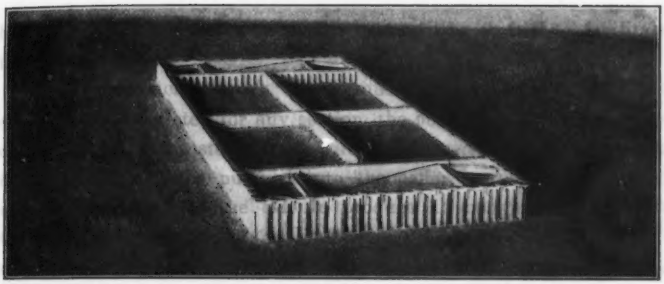

FIG. 17.—COFFER-DAM-BOAT IN FLOODED CONDITION.

FIG. 18.—COFFER-DAM-BOAT DETACHED FROM BASE, AND GATES IN SIDES OF COFFER-DAMS OPEN TO CLEAR SIDE-WALLS OF COMPLETED DOCK SECTION.

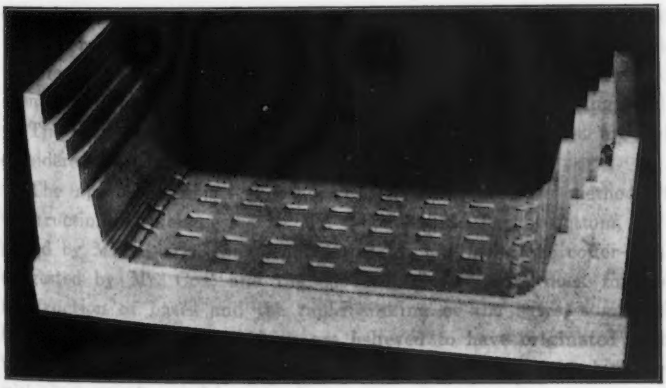

FIG. 19.—ISOMETRIC VIEW OF COMPLETED SECTION OF DOCK.

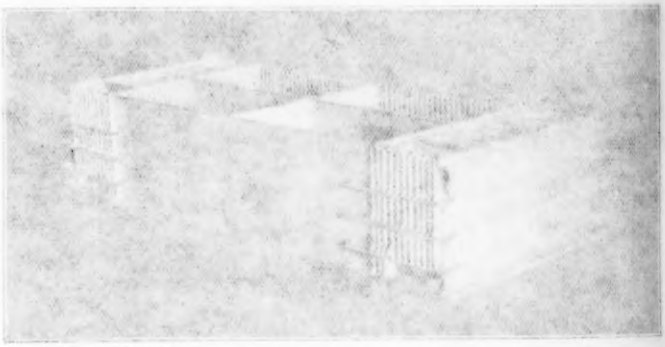

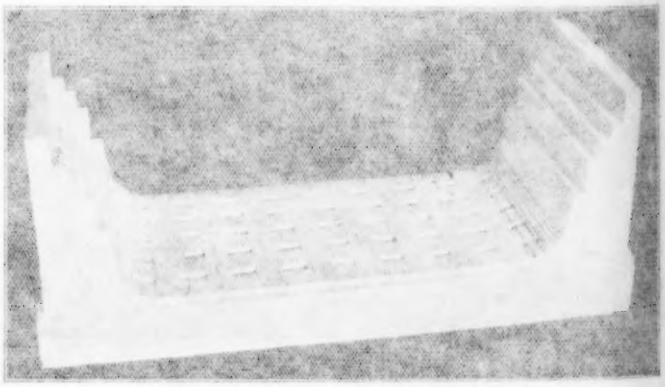

bracing between the stools under the boat will be shifted to facilitate the concrete work.

When the concrete work which must be performed within the coffer-dam is completed for any section, the bolts connecting the stools of the boat with the steel frame will be removed and the coffer-dam flooded; water will be pumped into the coffer-dam space to a level a little above that of the tide to produce an outward pressure on the walls of the coffer-dam to liberate any temporary bracing which may have been placed between the concrete and the walls of the coffer-dam; the exterior bolts will then be removed and the water pumped out of the boat; when the boat is practically dry the side-gates in the ends of the coffer-dam will be removed to enable the coffer-dam-boat to be floated over the concrete side-walls of the completed section. Fig. 18 shows the coffer-dam-boat floating at minimum draft, with the coffer-dam gates opened ready for the coffer-dam-boat to be removed from a completed section to repeat the cycle of operations.

Fig. 19 shows an isometric projection of a completed section. The rectangular spaces in the floor are the spaces in which the stools rested; they will be filled with concrete when the dock is unwatered. The concrete below the surface of the floor to the top of the steel frame is 15 in. thick.

The semicircular wall at the head of the dock will be built on a bed which will be prepared within the steel coffer-dam prior to the detachment of the coffer-dam-boat from the base for the inner section.

After completing the sixteen sections of the dock, and the pump-well, the open spaces between the sections and the well will be sealed with tremie-placed concrete or small coffer-dams, and the dock unwatered. The open spaces will then be completed under dry and open conditions, and the side-walls will be carried to the coping level.

The portions of the work which have not been described are not considered to involve any special construction difficulties.

The approved design incorporates the sectional-boat method of construction, first suggested by Mr. Cox in 1911, the flat bottom, suggested by Mr. Harris, the use of water for weighting the coffer-dam, suggested by Mr. Cox, and the use of a floating dry dock for the construction of bases and the rapid sinking of the bases, suggested by Mr. Noble. Features which are believed to have originated with the writer include the use of structural steel frames in combination with concrete for making the bases, instead of reinforced concrete;

the transporting or carrying device to insure the bases against sinking or loss from the time they are released from the floating dock until they are finally settled in position in the bottom of the dock excavation; the facilities for readily adjusting the draft and trim of the bases while being moved to position and being settled; the provision which enables the repeated settling and raising and settling of any base, as may be desired, to secure accurate alignment and satisfactory bed; the elimination of all timber sheeting and nearly all timber bracing required for construction of the dock sections, with large reduction in cost and building hazard; the elimination of practically all tremie-placed concrete without involving endangering conditions; and the use of voussoir blocks in building the semicircular wall at the inner end of the dock.

The elimination of tremie concrete is considered a most valuable feature of the approved plans, inasmuch as there can be no absolute certainty that concrete deposited under water will possess the uniform degree of perfection which is essential if the dock is to be satisfactory when completed. Although other methods which have been suggested would obviate the need for tremie concrete, the results would be accomplished at the expense of serious building hazards involved by long periods of flotation while unwieldy boats of more or less temporary construction were being loaded with large masses of concrete, and by the repeated construction and use of large timber coffer-dams. The finished details of the plans represent the combined studies of the several members of the Corps of Civil Engineers who have worked on the problem, the contractors' engineers, and the Bureau's technical assistants.

Conclusion.

The writer takes pleasure in mentioning the valued assistance rendered him in the preparation of this paper by Mr. E. R. Gayler, and Mr. Joseph Michaelson. The record would not be complete, however, without special tribute to the late Alfred Noble. He should be given the credit for final success in bringing about a resumption of work under most amicable arrangements between the contractors and the Government, in accordance with plans which apparently provide the greatest practicable safeguards in the expenditure of the country's funds with every promise of the ultimate satisfactory completion of the greatest public work of the United States Navy.

DISCUSSION

Mr. Fowler.

CHARLES EVAN FOWLER,* M. AM. SOC. C. E. (by letter).—The Profession is greatly indebted to Mr. Stanford for his comprehensive paper on the Pearl Harbor Dry Dock.

The construction of graving docks in the United States still remains very much of a novelty, although abroad it is a very common occurrence. The very fact of their novelty, although making the paper of greater value, is undoubtedly one of the causes of trouble in their construction, as neither the Government nor the contractors are able to obtain engineers or workmen who are experienced in their design or construction.

The sites for naval dry docks are seldom chosen by the designers, except within very narrow limits, but are selected for strategic, political, or other evident reasons, entirely aside from their suitability for a structure of such magnitude. Then, again, the time allowed for designing is usually all too short for a comprehensive study of the conditions which will be encountered, and must be taken into account in both the design and construction.

Imagine, too, the slight chance which bidders have to study carefully and digest the problem in the short time provided by the law for preparing and submitting bids. The bidder, of course, is in no way obligated to verify the borings, which, if made by the wash-boring process, are almost always unreliable and likely to suggest conditions which properly made core borings would show to be non-existent.

The construction of graving docks in England is very common in connection with projects for immense wet docks, and, in some cases, they are constructed parallel to the lock entrances to the wet dock, as at Tilbury, so that in case of an accident to the lock, they can be used as entrances to the wet dock. Comprising as they do a portion of such a great system of construction, it is natural that more time should be afforded in which to study the conditions and design, and consequently less trouble would be encountered during construction.

After reading Mr. Stanford's paper, the writer can see no reason for changing the conclusions reached some years ago, that the proper method of constructing a dry dock where conditions are unfavorable, as was the case at Mare Island and at Pearl Harbor, would be to do it under water, which was done successfully at Kobé, Japan, and has been fully described† by the writer.

That there may be serious objections to such a method is granted, but they are not such as cannot be readily overcome by the careful designer and constructor. The paramount objection is that of obtaining

* Seattle, Wash.

† "Sub-Aqueous Foundations," Chapter XXX.

Mr. Fowler.

good results in depositing concrete in sea water, and the writer's experience leads him to believe that, if made in this way, with proper equipment and care, the concrete will be just as good as, or better than, if deposited in the dry, and at no increase in cost.

The method used should be that known as the "Detroit Tunnel Method", and the tremie should be kept buried in the concrete at all times and moved around slowly, so that the concrete does not have to run to any great distance and does not come to any extent into contact with the water. This will obviate the washing of the cement, laitance, and consequent poor concrete.

Strange to record, perhaps, the writer's experience has shown that a smaller pipe for the tremie than any of those used at Pearl Harbor has given better results. That used at Tacoma for depositing concrete in depths between 50 to 60 ft. was of 10-in. lap-welded, screw-jointed pipe. This was successful because the interior was smooth, the joints allowed no water to leak in, and the tremie was light enough to allow it to be moved easily and properly. This work has been described by the writer,* who has demonstrated that riveted pipe is very objectionable.

Where riveted pipe has been used, it has always been larger and has had to be kept filled above water level, which is unnecessary with the smooth, screw-jointed pipe. For shallow depths, a square wooden pipe, with its smooth interior, will be found to be very good.

Although it is undoubtedly best to use a 1:2:4 concrete for under-water work, one of 1:3:5 will be found to give good results with a proper tremie and with proper care.

A few years ago, and simultaneously with its use at Kobé, the writer proposed the under-water method for a large dry dock in a mud foundation, with piling cut off under water, believing it to be the surest way of preventing trouble due to upward pressure. Practically all the weight is available when the dock is pumped out, the anchorage of the piling is effective, and a steel mat of reinforcing bars can be placed in under-water concrete, if necessary, to resist the arch action in a wide dock.

Experience has shown† that where piles are driven with a cast-steel follower cap to which their heads are fitted, they are left in better shape than when cut off under water.

The box type of coffer-dam was proposed for the case mentioned, such as that used at Mare Island and that first used at Pearl Harbor, but the very great care necessary to build a fairly tight dam and the danger of just such a failure as was realized at Pearl Harbor, would seem to make it a grave question whether its use is ever advisable.

* *Loc. cit.*, Chapter X.

† *Loc. cit.*, p. 202.

Mr. Fowler.

Conditions might be such that neither the under-water nor the box coffer-dam method would seem advisable, and it might then be asked, are there no other plans of construction possible than the phenomenal scheme proposed by Mr. Noble or the monumental one that has been adopted? Although evidently there are many answers possible to such a question, the logical one would seem to be that a movable pneumatic caisson or diving bell might be used to construct the dock in sections, joining them together with tremie concrete, as proposed in the Gayler block design, or by the use of a movable joint coffer-dam, as proposed for the adopted method, and which presumably is similar to that used for the Antwerp Quay Wall.* Although the Noble plan and the adopted plan are undoubtedly sure methods, and for this reason may prove the cheapest, it does not seem to be presumptuous to call attention to the foregoing ideas which may prove worthy of adoption in some future case.

The vital points are that more time should be allowed for the study and design of such large structures, and that more time should be given the bidders in which to study and estimate on the work and submit proposals.

Mr. Taft.

HARRISON S. TAFT,† ESQ. (by letter).—In view of the article entitled "Floating Concrete Caissons" by the writer and Mr. O. D. Jones,‡ Mr. Stanford's paper has been read with the deepest interest. Notwithstanding the varied uses that have been made of floating concrete caissons, the work now being done at Pearl Harbor under the direction of Mr. Stanford's department stands out as one of the most extensive and most scientifically worked out applications of the art, up to the present date; and its successful accomplishment will be another triumph for American engineering. Although a lengthy discussion of the floating concrete caisson problem by the writer would be superfluous, there are several points in this worthy paper on which, it is thought, a few words can well be said.

Mr. Stanford mentions the serious defects found in the concrete first placed under water by tremie operations, and seems to lay special emphasis on the desirability of excluding salt water from within a mass of freshly deposited concrete. As is well known by those most experienced in placing concrete under such conditions, not only does the infiltration of sea water into it cause the formation of the white chalky substance which prevents the proper formation of the plastic concrete into a dense, water-tight, and homogeneous mass, but inexperience in the operation of the tremie leads to results that are practically worthless—that is, in a great many cases. It is of interest to note that, in the construction of a graving dock by Japanese engineers,

* *Loc. cit.*, Fig. 427.

† Seattle, Wash.

‡ *Professional Memoirs*, March–April, 1915, p. 145.

Mr. Taft. special attention was given to the problem of preventing the intermingling of sea water with the green and freshly placed concrete in depositing, under water by the tremie process, a thick layer of concrete as a "seal" for the base of the floor of the dock. The method they used was the reduction of the saline contents of the sea water to a minimum by the introduction into the enclosed coffer-dam, of fresh water from the city water supply, an operation that is said to have met with marked success, and resulted in a first-class concrete sealing job. The coffer-dam was afterward unwatered and the remainder of the dock was completed in the dry with equally marked success. Whether such a mode of procedure would have been possible, or would have eliminated some of the troubles at Pearl Harbor, the writer is not in a position to state.

Mr. Stanford's statement that briquette tests showed that concrete mortar must not be of a less than 1:2 mixture, for a successful use under sea-water conditions, coincides with the results of other experiments by prominent engineers.

The writer notes that Mr. Stanford does not state the chemical composition of the cement being used at Pearl Harbor; it would be of interest if he would furnish some data as to whether he is taking any steps to obtain a special manufactured cement for the work, or is using the daily commercial output of the mill.

The author mentions the rapidity with which the concrete was mixed, namely, batches, of some 1.85 cu. yd. each, at the rate of 40 to 50 per hour, equivalent to a batch every 72 to 90 sec. (approximately 1¼ to 1½ min.). Though it seems to be the aim of some engineers, and especially of contractors, to turn out the greatest possible quantity of concrete per hour, without regard to the time of actual mixing, a great many are beginning to feel, and note in their specifications, that some limit should be put on the length of time a batch is kept turning in the mixer, especially when the concrete is to be exposed to contact with sea water, and still more especially when placed by a tremie. Though a 5-min. mixture may be excessive, it is without doubt far better to mix the concrete as long as 5 min., or even longer, than to shorten the time of the mixing to such an extent as to have the supposedly mixed concrete discharging before the last of the unmixed ingredients have been put into the mixer, a mode of procedure that most surely will cause future troubles, and in a very short time at that, if the concrete is used in structures in contact with sea water. A period of fully 3 min., as called for by some engineers, or a definite number of turns of the machine, such as 25, as used on one Government job of magnitude (all reckoned from the time that the last of the necessary ingredients have entered the mixer), will no doubt give far better concrete than the speed quoted by the author. It is possible that the rate of mixing, as well as the lean concrete, and the inexperi-

ence in using the tremie, account for the poor and worthless results Mr. Taft.
Mr. Stanford says were obtained with the concrete placed in Crib II.

The writer has at times been asked as to the holding-down power of a pile having its head encased in concrete, and as to whether the head would be pulled out of the concrete or the pile pulled out of the ground by the lifting of the concrete structure. One case, at least, which has been cited, was the washing out of a bridge by flood waters, whereby some of the piles were broken off at the under side of the concrete base and others were pulled completely out of the earth and remained embedded in the concrete as when the structure stood erect in its proper position. As well known, the figure usually adopted to determine the carrying power of a pile in compact sands is about 660 lb. per sq. ft. of pile surface, equivalent to about 1 ton per lin. ft. for a 12-in. pile. On the basis of 47 tons upward pull, as noted by Mr. Stanford, and a 5-ft. embedded head, for a 12-in. butt, the calculated resistance is about 3 tons per sq. ft. of contact surface. The resistance, for a pull to destruction of the bond, is apparently unknown.

In giving the results of the experiments with a tremie, Mr. Stanford has added valuable material to a subject on which engineers in actual charge of work have had but few accurate data. In several articles in engineering literature during the past few years, facts of considerable worth have been given to the contracting engineer, as to the best size of tube, etc., and as to operation; but all such data, even that of Mr. Stanford, do not seem to have furnished the engineer with a suitable description of the method of first loading the tremie, in order to prevent absolutely the intermingling of the concrete and the water in the tube. In other words, there is no improvement over the old-fashioned methods of driving the water out of the tube during the loading period, and at the same time keeping the initial loading of the tube and its going into operation under absolute control, irrespective of the depth of the water or the size of the tube.

In depositing the subaqueous concrete around the tubes of the Detroit River Tunnel, "a wadding of cement sacks was at first placed in each tremie on top of the water to prevent the concrete from dropping through while filling the pipe".* Batches of concrete were then poured in on top of the wadding, the slight raising of the tremie permitting part of the water to run out and the stopper to run part way down the tube. More concrete was then poured in, etc., until the stopper finally passed out of the bottom of the tube and the outflowing concrete formed a seal around it. After some tests it was found that dry concrete could be used to take the place of the sack wadding, and such a mode of procedure was adopted after the work was well under way.

* *Engineering News*, March 17th, 1910, p. 320.

Mr. Taft.

In place of a sack wadding as a stopper, some engineers have used paper bags filled with dry concrete; others have used a wadding made by dumping in a pail of sawdust on top of the water before pouring the concrete into the hopper of the tremie. Mr. G. W. Rear has devised a mode of using a stopper consisting of some 7 or 8 in. of planer shavings covered with 1 in. of cement, the buoyancy of the shavings and the resistance of the column of water below preventing the stopper from falling too rapidly down the tube, the concrete itself acting as the seal. As stated by Mr. Stanford, at Pearl Harbor, a bag filled with straw was inserted and descended in the tube when the concrete was placed above it.

Although the foregoing and other methods of loading a tremie usually call for the assembly of a large quantity of concrete for the initial pouring, they also leave the operation practically uncontrolled by the men in charge, and the discharge of some tons of weight into the tremie at one operation is apt to set up considerable vertical movement, especially when the tremie is hung from the end of a boom on a scow, thus interfering seriously with successful loading.

The introduction of such matter as sawdust, shavings, straw, paper bags, etc., may be of absolutely no importance in the placing of subaqueous mass concrete, yet in cases of reinforced concrete columns, from 3 to 4 ft. in diameter, as used at San Francisco and in the Puget Sound Navy Yard, the introduction of such foreign matter may affect seriously the permanency of the structure. The elimination of all foreign matter from concrete placed in sea water should be absolutely insisted on, if the best results are to be guaranteed. It was in connection with just such a guaranty that the writer was led to devise an all-concrete stopper, mechanically controlled in its descent through the tube, even though the lower end of the latter was far above the mud line and freely swinging in the water. A brief description of this stopper, it is thought, will be of interest.

As shown in Fig. 20, the stopper is of concrete, having a circular disk for its base and a frustum of a cone for its head, the two parts being made monolithically. It is built in two parts, with a hole at the center, so as to permit them to be placed around a bolt and rest on a washer at the pointed end. The diameter of the stopper should be such as to suit the tube, with sufficient clearance to permit of a free descent. The bolt is suspended by a wire or rope running to some kind of controlling device, such as a winch, to provide for lowering the stopper through the tube. If desired, a plastic washer of soft leather or rubber may be placed at the top of the stopper, as shown. The two parts of the stopper are first placed around the bolt in the upper part of the tube and lowered slightly. Concrete is then poured in above, and the stopper is slowly lowered as more concrete is poured in above it. When the stopper has reached the lower part of

the tube and is ready to pass out, the tremie having been raised sufficiently above the ground, the unbalanced couple formed by the supporting bolt and the weight of the concrete above the stopper causes the two halves to fall apart and permit the outflow of the concrete to form a seal about the bottom of the tube, the hopper having been fully loaded in order to prevent any interruption in the column of concrete in the tube after the opening of the stopper. The bolt is then withdrawn and kept for the next loading. As the two parts of the stopper remaining in the mass are of concrete, there is no foreign matter in the deposited concrete, as is the case with some of the older modes Mr. Taft.

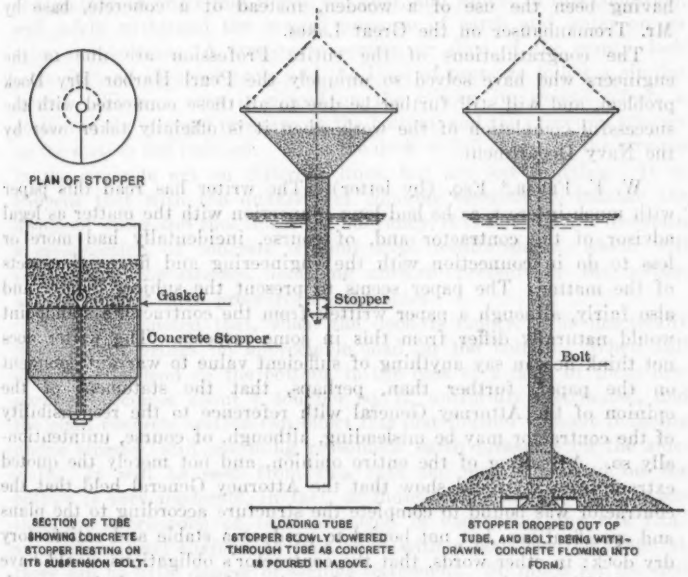

FIG. 20.

of operation. Though the writer has not yet had an opportunity for an extensive trial of this device, it appears evident that it provides an absolute means of preventing any intermingling of the water and the concrete, and at the same time there is positive control of the whole operation.

Inasmuch as the prime factor in securing a successful use of concrete under sea-water conditions is a pre-moulded, air-cured structure, as pointed out by the writer,* there can be no doubt that the use of structures of such a type by engineers is bound to become more

* In "Floating Concrete Caissons."

Mr. Taft. general, as the years go by, the successful culmination of the Pearl Harbor project, no doubt, doing much to encourage the engineers of America in a still further and more extensive use of such a mode of construction and in a more liberal utilization of concrete in harbor development and sea structures. Though it is a matter of record that the first floating concrete caisson was built without any reinforcement whatsoever, all subsequent ones have been on a typical reinforced basis. The extensive use of structural steel, as adopted for the Pearl Harbor Dry Dock, apparently is the first in such a structure, thus marking the fourth step in the development of the art, the third having been the use of a wooden, instead of a concrete, base by Mr. Tromanhauser on the Great Lakes.

The congratulations of the entire Profession are due to the engineers who have solved so uniquely the Pearl Harbor Dry Dock problem, and will still further be due to all those connected with the successful completion of the work when it is officially taken over by the Navy Department.

Mr. Frear. W. F. FREAR,* ESQ. (by letter).—The writer has read this paper with much interest, as he had long connection with the matter as legal advisor of the contractor and, of course, incidentally had more or less to do in connection with the engineering and financial aspects of the matter. The paper seems to present the subject lucidly and also fairly, although a paper written from the contractor's standpoint would naturally differ from this in some respects. The writer does not think he can say anything of sufficient value to warrant comment on the paper, further than, perhaps, that the statement of the opinion of the Attorney General with reference to the responsibility of the contractor may be misleading, although, of course, unintentionally so. A reading of the entire opinion, and not merely the quoted extract from it, would show that the Attorney General held that the contractor was bound to complete the structure according to the plans and specifications, but not bound to produce a stable and satisfactory dry dock; in other words, that the contractor's obligations would have been fulfilled if the structure had been brought to completion according to the plans and specifications, even though it should collapse afterward.

It was a matter of gratification, both to the Government and the contractor, to be able to arrange for the completion of the work on the new plan under a supplemental agreement, and it is to be hoped that in due time a dock satisfactory to all parties will result.

Mr. Reed. P. L. REED,† M. AM. SOC. C. E. (by letter).—Supplementing the detailed account of the Pearl Harbor Dry Dock given by the author,

* Honolulu, Hawaii.

† Charleston, S. C.

as regards location, geology, history, finances, design, and construction so far as it has progressed, a few general features may be emphasized. Mr Reed.

There have been two primary problems in the design of this structure: First, to design a dry dock which would safely dock ships of specified maximum dimensions, and would withstand indefinitely the stresses brought on it in this service; second, to design a dry dock which could be safely constructed on the Pearl Harbor site.

In this case, the first problem was much the simpler. Given the interior clearances, it is required to design a concrete box which will weigh when empty approximately as much as the water it displaces at high tide, in order that it will not float, and which, in this condition, will safely withstand the inward pressure of earth and water on its sides and bottom. A transverse section or slice of the empty dock is, in fact, an inverted arch, and the lines of pressure follow a similar course. When a ship is placed on the blocks, its weight offsets a portion of the upward pressure on the bottom, and the principal stresses on the section are reduced. When the dock is full of water, the stresses in the concrete act on different lines, but are less exacting. It so happens that with the quantity of concrete required to balance the displaced water and thus offset the buoyancy, it is not difficult to obtain a cross-section of concrete without steel reinforcement, which will safely carry the stresses, assuming uniform pressure on the bottom and reasonable earth pressures on the sides.

It will be noted that, when the dock is empty, it is practically floating and brings no appreciable load on the bottom. When full of water, the load on the bottom, in the case of a dock of these proportions, becomes about 1 ton per sq. ft. uniformly distributed, and the plain concrete section can effect this distribution without inducing undue stresses, still assuming reasonable earth pressures on the sidewalls. It will be seen from this that the maximum load on the bottom is very moderate, in fact, as indicated in the paper, it is less than the overburden of earth removed in excavating the site from an original level surface, so that, even with a poor bearing material, there can be little danger of serious settlement. So much for the first problem.

The second and much harder problem was to design such a concrete box that it could be positively and safely constructed in a freely water-bearing soil where a coffer-dam was found unavailing, as the water came up through the bottom. As the empty concrete box weighs as much as the water displaced when it is in place on the bottom, it could not be constructed in whole or in complete sections and floated to place, as has been done with some concrete caissons and sea walls, and it is very undesirable to deposit concrete under sea water where it can be avoided. What has been done in the adopted design, as explained in detail in the paper, is to provide a portable floating steel

Mr. Reed.

coffer-dam by which transverse sections or slices of the dry dock can be partly constructed on a floating dock, floated off, sunk in place, and held down by a tank of water while the sections are being completed in the dry. This method of construction brings in temporary stresses which are greater than those which the finished dock must sustain, and a large quantity of steel framing and reinforcement is required, which remains in the finished dock and increases its strength correspondingly, but which would not be necessary, except for the unusual method of construction required.

The steel coffer-dam combined with and surrounding the steel box which serves alternately as a water tank to hold down the uncompleted, and therefore buoyant, sections of the dock, and as a float to lift the coffer-dam as a whole from a completed section and place it on a new dock section partly constructed in the floating dock, is the ingenious invention of the author to meet the unusual conditions described, and constitutes an effective and novel combination of construction appliances.

Mr. Harris.

FREDERIC R. HARRIS,* M. AM. SOC. C. E. (by letter).—The writer is much interested in this paper on the Pearl Harbor dry dock, giving as it does a description of the geology of the location, the history of the design, the difficulties encountered in the construction, and the evolution of the plan on which the work is now being done.

In the latter part of March, 1913, shortly after the disastrous collapse of February 17th, the writer, under orders from the Secretary of the Navy, visited Pearl Harbor with Mr. Stanford, and spent 11 weeks investigating and examining the work, and inquiring into the causes of failure. Mr. Stanford was then, as he is now, Chief of the Bureau of Yards and Docks, and had many duties and responsibilities other than this particular work, so that, during the 2 weeks that he remained on the Island, much of the planning for a systematic investigation, together with the charge of the actual work thereof, was directly in the writer's hands. After Mr. Stanford's departure, in addition to this work, the writer, with E. R. Gayler, M. Am. Soc. C. E., the officer in charge, and Mr. Gordon, was a member of a Board to investigate the foundation conditions of the site, and this work was carried on independently of the principal investigation, although many of the data obtained for the latter were used in connection with the work of the Board.

Geological.—In addition to the comment in the paper on the geological formation, the writer would like to bring out the impression, made by conditions on the Island of Oahu and other islands of the Hawaiian group, on an engineer familiar with work on the main con-

* Philadelphia, Pa.

tinent, where his experience would furnish little or no precedent to guide him in an understanding of the Hawaiian soil and foundation conditions. As an illustration, ordinarily, in the older main-continent formation, when the over-burden of earth and soils has been removed and rock is encountered, and after proper precaution has been taken to be sure that it is not a boulder, the assumption is well warranted that it is ledge rock and extends indefinitely downward. In the Hawaiian Islands, frequently a volcanic rock is encountered, and soils or disintegrated rock are found below it. Geologically, the islands are very recent, and earth or soil similar in character to the soils of the continent would yield and compact considerably under a foundation pressure, which, in the United States, would be considered thoroughly safe, a probable and logical explanation being that such surface soils, or soils comparatively near the surface, have never been subjected to the great pressures of an over-burden, later moved by erosive and weathering action. They are so recent geologically that there has been no opportunity for the working over with mechanical and chemical changes that will occur with the passing of future ages. Mr. Harris.

Borings.—On page 257, and in what follows, Mr. Stanford has mentioned the exploration borings, made under the direction of C. W. Parks, M. Am. Soc. C. E., in 1908, and the check borings, which were made under the writer's directions. In further explanation of this information, the writer, for a long time, in common with many other engineers, has believed that it is frequently difficult fully to appreciate and understand subsoil conditions and formations from the information obtainable and available by the wash-boring method of exploration, especially when the investigation attempts to bring out the compactness and imperviousness of the soils in place, the difficulty being emphasized by the recent volcanic formation of these islands and the extreme uncertainty of properly classifying materials brought up by wash-borings where experience and judgment would be predicated on continental formations.

Previous to sailing for the Islands, the writer had a conference with A. L. Parsons, M. Am. Soc. C. E., on this matter, and, on arriving, received from him some advertisements and descriptive matter relative to the Calyx double-core barrel drill for soft ground exploration. An attempt was made to secure such a drill, but the nearest one was then in El Paso, Tex., and to obtain it would have involved considerable time and delay. A smaller rotary drill of this type was in use by the army engineer in Honolulu, but it was not furnished with a double-core barrel, so that it was attempted to secure solid cores by the driven-pipe method, as described by Mr. Stanford on page 258. The writer was satisfied that the results being obtained closely represented the subsoil conditions, but the earlier reports from Mr. Gayler, and

Mr. Harris. the opinion of the contractor's engineer, Francis M. Smith, M. Am. Soc. C. E., appeared to be that the soils underlying the work were of a semi-liquid or plastic character, and that the failure of the work had been caused by liquid mud pressure, that is, the pressure of the material composing the banks on the lower so-called lava mud. Figs. 8 and 9 are typical of the cores obtained from the driven pipe. A great many cores and samples obtained in the boring operations show no evidence of plasticity or a liquid condition, but Mr. Smith believed that possibly the driving of the core barrel ahead of the casing might have compacted the material, especially the so-called lava mud, and driven out the water, so that although the obtaining of cores was proceeded with by the driven-pipe method, arrangements were made to use the rotary Calyx drill. Four borings on the bank were made by this drill, the object being to check up by this method of boring, which did not involve compacting the cores. The cores were inspected as they were secured, and their specific gravity or weight submerged in sea water was taken, the object of which will be made clear hereinafter.

In addition to obtaining the solid cores and their weight in sea water, it was decided to investigate the porosity or perviousness of the subsoil, especially to locate, if possible, continuous impervious strata by permeability tests. In some recent core borings in ledge rock, the perviousness or leakage has been ascertained with two plungers or pistons, closely fitting the bore, by supplying water under pressure to the space between them. As the operations were carried on at various elevations, it was, of course, impossible to apply this method, and the following expedient was adopted: Directly after withdrawing the driven-pipe core barrel, the casing pipe was filled with water to a height of several feet above tide level, thus subjecting the subsoil at the foot of the casing pipe to a pressure or head of several feet of water, and then the loss of water in the casing pipe was observed for a time. As the joints in the casing pipe were not leaded, undoubtedly, in many instances, slight leakage occurred, so that very small outflows of $\frac{1}{8}$ in. per min. or less were considered as representing practically an impervious soil. These observations were continued and recorded. The result was a strong indication that the so-called lava mud and this same material mixed with some coral was impervious and continuous over the entire area, forming a complete water-tight diaphragm. The coral materials above this lava formation were somewhat pervious, and those below it were more pervious, and, in instances, quite freely water-bearing. The indications in all these observations were that the water present in the soils was under a ground-water or tide-water head equivalent to about that of tide level. It is stated by Mr. Stanford that "the character of the mud stratum has been of vital importance throughout

this work." Although, geologically, it might be termed "mud", its physical characteristics would be defined more clearly to an engineer by the designation "clay". Under the microscope, it was more granular, the contained water was hygroscopic, and it was deficient in aluminum, as compared with continental clays. In making and burning briquettes, in some instances they were partly vitrified, and in others powdered and disintegrated. Samples immersed in water did not in all instances show the characteristics of continental clay, nevertheless, they did not dissolve readily and break up, but preserved their shape to such an extent that it was possible to immerse them in water and obtain their specific gravity and still retain them as effective samples. Plate X, made up from the 1913 borings, indicates the probable strati- Mr. Harris.

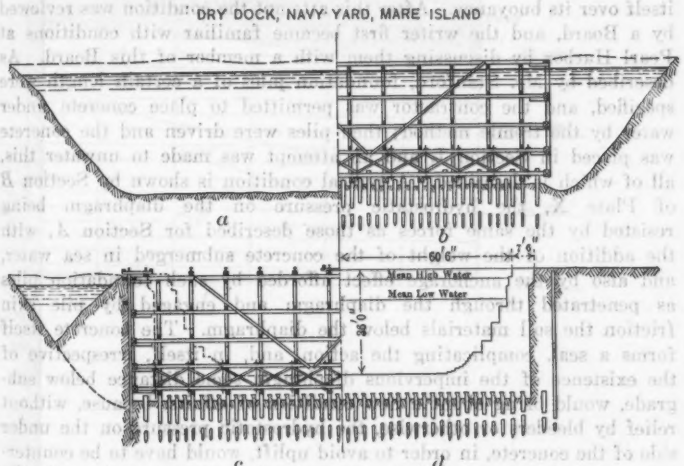

FIG. 21.

fication on the site of the structure. It is possible, of course, that the so-called lava mud stratum was not continuous and complete, but the borings appear to indicate that it was. The cross-hatched, shaded portion of the stratification is the apparently impervious stratum or diaphragm. It will be noted that at a considerably lower elevation, beyond the depth of direct interest in the investigation of this work, a somewhat similar stratum of great depth is found.

Design and Construction.—Mr. Smith, in charge of the work for the San Francisco Bridge Company, had successfully completed the dry dock at Mare Island, Cal., previous to taking charge of this work, the method of construction being shown in Fig. 21, in four stages, which are largely self-explanatory. The work was completed by

Mr. Harris.

making the excavation, building large timber cribs, sinking these, driving around the periphery heavy timber sheet-piling, backing this up with the earth back-fill, and then pumping out the interior. A similar method was adopted for this dock, it being planned to use five sections or cribs, as explained by Mr. Stanford.

Section *A* of Plate X is typical of subsoil conditions in Section I, and shows the operations there in the first attempt to unwater it, called Failure No. 1. The rising of the crib can be explained by the removal of the weight of water from its interior—the hydrostatic pressure on the under side of the diaphragm being resisted by the weight of the water left in the interior of the crib, the weight of the saturated soil above the diaphragm, and the excess weight of the crib itself over its buoyancy. After this attempt the condition was reviewed by a Board, and the writer first became familiar with conditions at Pearl Harbor by discussing them with a member of this Board. As described by Mr. Stanford, foundation piles of a certain length were specified, and the contractor was permitted to place concrete under water by the tremie method; then piles were driven and the concrete was placed in Section I, and an attempt was made to unwater this, all of which is described. A typical condition is shown by Section *B* of Plate X, the hydrostatic pressure on the diaphragm being resisted by the same forces as those described for Section *A*, with the addition of the weight of the concrete submerged in sea water, and also by the anchorage effect afforded by such foundation piles as penetrated through the diaphragm and engaged by pile skin friction the soil materials below the diaphragm. The concrete itself forms a seal, complicating the action, and, in itself, irrespective of the existence of the impervious diaphragm some distance below subgrade, would bring about a new condition of affairs, because, without relief by bleeders or otherwise, the hydrostatic pressure on the under side of the concrete, in order to avoid uplift, would have to be counterbalanced by the weight of the water in the interior of the crib, the excess weight of the crib, the submerged weight of the concrete seal, and the anchorage effect of the foundation piling, in turn dependent on the submerged weight of the mass or prism of earth engaged by these foundation piles. As given by Mr. Stanford on page 241, the average length of the 1 966 piles driven in Section I was 23.78 ft., and although the resistance to up-pull for a single pile is dependent on the skin friction of the pile, or the actual mechanical anchorage in the case of piles with enlarged bases, in either case it is limited by the weight submerged in water of the conical but irregular masses of earth surrounding the pile that would have to be lifted; the anchorage effect in a group of piles driven closely together would be less than the sum of the individual effects of a like number of single piles, and in turn would be limited by the irregular prism or mass of

earth pinned together or engaged by pile skin friction, so that the exact effect of the anchorage piles would depend not so much on the average length of the piles as on the relation of the long piles to the average. Mr. Harris.

In making a check computation on Failure No. 2, the rising of the crib was noticeable with water removed from the interior to from 32.8 to 34.3 ft., and this would give the mean depth or thickness of the mass of earth lifted as 22 ft., as compared with an average length of piling of 23.78 ft.

The next failure, or rather the final collapse, occurred on February 17th, 1913, in Section II, the typical conditions of which are shown by Section *C*, Plate X. As stated by Mr. Stanford, the average length of piles in this section was 20.53 ft., giving by similar computation the mean depth of the mass of earth lifted as 18.5 ft.

Referring to the sixty 2½-in. vertical drain-pipe bleeders described by Mr. Stanford, on examination of Section *C*, Plate X, it will be readily seen that these merely served to drain the confined soil above the so-called lava mud diaphragm, and did not help in any way to relieve the pressure under the diaphragm itself, and to that extent their effect toward averting failure was negligible, if of any use at all. The existence of the bleeders would serve to relieve more or less, and decrease, the hydrostatic pressure on the under side of the concrete seal, but with the existence of an impervious stratum or diaphragm some distance below sub-grade, by draining out the ground-water in the coral above the so-called lava mud, they might decrease the total weight of ground-water above the diaphragm, and to that extent decrease the resistance to uplift on account of the pressure below the diaphragm, and in this way possibly bring about an actual upward movement earlier than would be the case if these bleeders had not been put in. It is extremely doubtful whether any such conditions existed, but it is readily seen that the value of the bleeders was negligible, as they affected the hydrostatic pressure exerted on the under side of the so-called lava mud stratum, which was practically impervious.

In the computations referred to, 54 lb. was taken as the weight of the soil immersed in sea water; an average of actual observations gave 60 lb., but this was reduced by 10% for possible compression in securing samples by the driven-pipe method.

Suggested Plans.—In June, 1911, after the failure to unwater Crib I, and before the change was made specifying foundation piles, with permission to place a certain quantity of concrete under water by the tremie method, the writer became familiar with Pearl Harbor dry dock conditions, and on June 11th, in correspondence with P. L. Reed, M. Am. Soc. C. E., a member of the Board, suggested

Mr. Harris.

that, if a tie were considered necessary for anchorage purposes, especially to provide for the construction condition, rectangular caissons be used instead of piles, in a manner somewhat similar to what was then being done on Dry Dock No. 4 at the New York Navy Yard, of the construction of which the writer was in charge, and called attention to the necessity, during this construction stage, of engaging by anchorage and a stratum or prism of earth of a mean depth of 35 ft., in addition to the submerged weight of an 8-ft. layer of concrete.

As stated by Mr. Stanford, the view was taken that the anchorage condition during the construction stages was a problem for the contractor, and it was doubtful whether any anchorage of foundation piles would be required for the completed dock. The Government, however, did provide for paying for foundation piles with an average penetration of 35 ft., with an arrangement for a price per linear foot, so that payment would only be made for lengths actually driven. The writer can state without hesitation that it was impossible to drive piles to a much greater average depth than was secured, which, in the case of Section I, was slightly in excess of 20 ft., and in Section II slightly less than 24 ft., so that perhaps the first suggestion for a change in plan was made by the writer when he proposed the substitution of pneumatic caisson piers and anchors. However, with the information available at that time, there was then apparently no serious reason for considering or adopting a costly change in plan.

In April, 1913, shortly after arriving in the Hawaiian Islands, and after becoming familiar with the conditions, the writer was strongly of the opinion that two general courses were available for the completion of this dry dock: First, following the lines up to that time proceeded with, by the construction in an open coffer-dam, holding down the structure during construction against uplift and flotation by added anchorage or weight, and, as such added anchorage could not be secured by driving deeper anchor or foundation piles, by either placing considerably more concrete by the tremie method under water before unwatering, or by adding weight in the form of rock ballast. The quantity of rock ballast that would have been required in one section was considerable, in fact, this plan seemed impracticable. The second plan was to adopt the familiar method often used in bridge pier construction, where the unwatering of the site and the building of an open coffer-dam is impracticable or undesirable; that is, the preparation of a level foundation and the sinking of the structure on this prepared foundation through the water without unwatering, that is, the use of floating coffer-dams or caissons. In February, 1910, while the writer was in charge of the dry dock construction at New York, he had suggested to Mr. Frederick Holbrook, of the Holbrook, Cabot and Rollins Corporation, the placing of the entrance of that dry dock by using a similar caisson, and had drawn up a tentative

METHOD OF CONSTRUCTION FOLLOWED BY CONTRACTOR
AND MODIFICATIONS PROPOSED TO CARRY IT OUT SUCCESSFULLY

plan for the work on these lines for the purpose of avoiding the construction of the usual open coffer-dam at the entrance. The plan was discarded as more expensive than that finally used. Further, in September, 1912, as an associate with William Barclay Parsons, M. Am. Soc. C. E., on a project for dry dock construction in South Brooklyn, the writer made studies, outline design, and estimates for a dry dock, using coffer-dams or caissons, building the dock in sections, and constructing these sections in one of the timber graving docks available at the Erie Basin plant. The writer had with him during his visit to Pearl Harbor one of these sectional sketches, and discussed the matter with Mr. Stanford, who then believed that it was not advisable or necessary to consider so elaborate a plan. He also discussed this plan with S. H. Hindes, M. Am. Soc. C. E., President of the contracting firm, and Mr. Smith. It is noted that Mr. Stanford, on page 269, states that the writer submitted two plans in a letter dated September 26th, 1913. It is believed that this is unintentionally misleading, as the writer, on his return from the Hawaiian Islands, at the end of June, 1913, in a report to the Secretary of the Navy, dated July 1st, 1913, and written some time before this in the Hawaiian Islands, states: Mr. Harris.

"In view of what has been developed on this work, it is quite probable that some method of construction dependent upon the use of either timber or reinforced concrete floating caissons would lend itself more readily to the construction of the dry dock on this site. I have in mind the possible dividing of the dock into ten sections, each caisson to be the full width of the dock and 100 feet long; concrete masonry work of the dock proper to be built in the dry in the interior of these boxes, the added weight assisted by weight of flooding water to sink these boxes or caissons to place upon the prepared pile foundation. In Sections 1, 3, 4, and 5, working chambers could be provided to be operated under air pressure, these chambers later filled with concrete surrounding the heads of piles already driven; in Section 2 all of the concrete masonry to be placed in the open, no working chamber or air pressure to be used, and the entire mass sunk in place as a gravity structure resting upon the prepared pile foundation, or the same method outlined for Section 2 to be used for Sections 1, 3, 4, and 5. This method of construction would permit of reinforcing with steel rods the floor or bottom of the dock so as to insure practically equal distribution of load over the dock bottom."

In the summary or letter of transmission, of July 1st, 1913, this statement was contained:

"With foresight and care it should have been possible, and still is possible, to employ the construction methods successfully that were employed previous to the failure, although certain modifications of the details of the design may be required to insure success of this method; such, for instance, as the placing of more concrete in the

Mr. Harris. bottom, and the application of movable weight to the bottom, all sufficient in amount to restore equilibrium during construction."

Immediately on the writer's return from the Hawaiian Islands, he started the development of the plan of the sectional floating caisson, recommendation of which was made in his report of July 1st, and on its completion it was forwarded on September 26th, 1913, the date referred to by Mr. Stanford. Only one plan was submitted—that of building the dry dock by sectional floating caissons—this plan, as may be seen by reference to Plates XII and XIII, being practically a sketch or pictured drawing. The details were not worked out, nor were any complete computations made. The other matter referred to as a second plan by Mr. Stanford was merely a graphical demonstration of the method used by the contractor, the probable cause of failure by unbalanced forces, and a suggestion as to how equilibrium could be brought about by the addition of under-water concrete, all shown by Plate XI. The adoption of the floating caisson plan was urged in this report as more certain and expeditious, and as a plan that, in view of the conditions developed by the failure of February 17th, 1913, would remove considerable of the danger and hazard. The time from July 1st to September 26th was taken up in preparing the picture sketches and consulting with several engineers and contractors of experience, in order to obtain from them their views as to the expense of this type of construction. The writer did not then hold the view, nor does he now, that anything so very new or remarkable was being recommended, but stated in his report:

"It is believed that this is an untried method for the construction of dry docks, but a method that has been frequently used for the placing of bridge piers, although probably not on so large a scale nor involving the placing of so many separate sections to be later connected and sealed."

Up to October, 1913, the writer had not been informed of the employment of the late Alfred Noble, Past-President, Am. Soc. C. E., by the Government, or that he had visited the Hawaiian Islands. Shortly after his return, early in October, 1913, Mr. Noble communicated with the writer and informed him of his visit, and that he was making some studies in the matter. The writer, at his request, forwarded to him the studies contained in the supplementary report of September 26th, Mr. Noble informing him that he already had his report of July 1st and had taken that out to Pearl Harbor with him. Mr. Noble never claimed that his recommendation, that the sectional floating caisson plan of construction be used at Pearl Harbor, was other than an elaboration and development of the recommendation of the writer, for how could he, as he took the writer's report of July 1st, containing the suggestion of this method, to Pearl Harbor

ISOMETRIC DRAWING OF DOCK IN COURSE OF CONSTRUCTION

METHOD OF CONSTRUCTION PROPOSED BY F. R. HARRIS

with him? In order to correct any erroneous impression, the writer would state that the information given, that Leonard M. Cox, M. Am. Soc. C. E., had in 1911 proposed the adoption of this method of construction, is news to him, as previous to his visit to Pearl Harbor and to submitting either the report of July 1st or the supplemental report of September 26th he had not found any such suggested plan among the papers and data given to him in connection with the Pearl Harbor investigation, the complete records of which were supposed to have been placed at his disposal, nor did he receive any intimation that such a plan had been proposed or existed. Mr. Harris.

The construction of bridge piers by this method is not new; it was applied successfully in breakwater construction in Zeebrugge, Belgium, in 1905; in Barcelona, Spain, in 1906; in Touapse, on the Black Sea; in Talcahuana, Chili, in 1908; in Bilbao and Bizerta; and in the United States under patent secured by W. V. Judson, M. Am. Soc. C. E., in Algoma, Wis., etc.; and on quay wall construction in Rotterdam; Norresundby, Denmark; Passau, on the Danube; and on a large and extensive scale in connection with pneumatic pressure and diving-bell work at Antwerp, Belgium. A dry dock built at Toulon, France, was constructed in a large steel caisson with a working chamber beneath; an extension to the dry dock at Livourne, France, by a single pneumatic caisson; and the dry dock at New York Navy Yard, constructed under the writer's supervision and design, by surrounding the site with a cut-off wall sunk into place in pneumatic caissons with central piers or anchors placed by the same method. The writer believed that the method recommended by him in the report of July 1st, 1913, was new and untried for dry dock construction, and on this assumption filed an application with the United States Patent Office on October 16th, 1913, and a patent was granted to him on April 6th, 1915. In making preliminary application for a patent, in August, 1913, the writer went on record with the Patent Office to the effect that the Government was to be granted free use of the patent for dry dock construction.

After the submission of the report referred to, the writer had no further connection with Pearl Harbor dry dock matters until January, 1914, when he was consulted relative to taking charge of the completion of the construction of this dry dock, on the same plan and construction methods being followed out previous to the failure. In his opinion this gave little promise of a successful completion of the dock, and involved great hazard and uncertainty. He then for the first time had the opportunity of examining the report and recommendations made by Mr. Noble, and was much gratified and reassured to ascertain therefrom that such a careful and conservative engineer held the same views, and had recommended the adoption of the sectional floating caisson construction for the dry dock. After con-

Mr. Harris.

siderable negotiation and conference. Mr. Cox and the writer were designated to prepare the necessary new studies and plans for the construction of the work. The writer devoted himself to the development of a suitable sectional floating caisson design, Mr. Cox confining his attention to some means of adhering to the original plan by using, for holding-down purposes at the sides, heavy concrete blocks, and at the center a steel ballast tank, very similar in general proportions and dimensions to the ballast tanks of the interior of the coffer-dam boat shown in Figs. 13 and 14.

Mr. Cox did not at that time inform the writer of having suggested or recommended the adoption of the sectional floating caisson method of construction, and in fact at that time was opposed to the adoption of this plan, although the writer has been more recently informed that at some time he discussed with the contractor's engineer, Mr. Smith, and made a rough sketch of a reinforced concrete floating dry dock that might be sunk as a unit and filled with concrete.

Mr. Stanford states on page 269 that the plan recommended by the writer was to construct the base or hull for each unit on launching ways. The writer believed that this would be the most economical and expeditious method of construction, but did not confine his recommendations within such narrow limits. In fact, in his applicaton for the patent, which was granted, he states:

"The floating box or caisson (*a*) shown in Fig. 1 may be constructed in the dry on inclined ways and then launched into the water, or it may be built in a shallow, excavated basin, this being then flooded, or by any other method whereby the floating caisson can be built in the dry and subsequently floated in the water to its proper position. Each box is then to be surmounted by a timber, concrete, or steel extension or lagging * * *."

The writer trusts that he may be pardoned for reference in this discussion to the patent granted to him. It was not taken out with any mercenary motive, nor with a view of any monetary return. He has honestly been under the impression, in so far as the adopted design used in the construction of this dry dock is concerned, that the recommendation for the use of the sectional floating caisson method of construction came from him. It would appear that it certainly first came from him after the failure of February 17th, 1913, when Mr. Stanford and the writer were instructed to investigate the failure of this work and recommend a means of overcoming such difficulties as might be found to exist, and when there was occasion to recommend a radical departure in the design. The writer believes that considerable remains to be done in carrying out the projected construction, from which by no means all the hazard and uncertainty have been removed. The construction of these large floating sections, the placing

METHOD OF CONSTRUCTION PROPOSED BY F. R. HARRIS

and removing of the floating coffer-dam, and the successful lowering of these sections to place on a properly prepared foundation involve the greatest difficulty, and call for considerable ingenuity, especially in order to avoid great and severe stresses in landing a section and bringing it to an equal bearing over the entire foundation area. Even the greatest care and foresight may perhaps not forestall an accident, resulting in the loss of an entire section and the necessity for its subsequent removal. In his original recommendation, the writer suggested that the foundation be prepared by sawing off piles with an under-water saw arbor, and that each section be provided with a base of 2 or 3-in. soft pine planking, so that when settled to place on the piles, a more or less even bearing would be secured by local crushing. He understands that the plan now adopted contemplates cutting off the foundation piles about 1 ft. below sub-grade and covering the entire area with broken stone, to be leveled off under water. Mr. Harris.

LEONARD M. COX,* M. AM. SOC. C. E. (by letter).—This paper covers so thoroughly the history of the Pearl Harbor Dry Dock construction to date, as well as the difficulties encountered in connection therewith, that little remains to be said in the way of discussion, beyond congratulating the author on the novel design finally evolved for surmounting those difficulties, and on the very valuable contribution he has made to the literature of maritime engineering. Mr. Cox.

As two plans were mentioned in the paper as having been suggested by the writer, it may be of some slight interest to explain these plans, or schemes, for carrying out the work, in a little more detail, and to describe briefly the conditions which led to their submission. The first hardly deserves the title of "plan", as it never progressed beyond the sketch stage, and for the further reason that conditions at that time (June, 1911) were not such as to warrant serious consideration of a change either in design or in method of construction. It consisted in the building, on floating submersible platforms, of a number of reinforced concrete floating docks, of convenient length and of a width corresponding to that of the completed dry dock, the depth of pontoons and width of side towers to be such as would allow ample room for placing the lining, when in position, as a part of the completed structure. The floating docks were to be towed to their destined locations and sunk, by the admission of water, as adjoining sections of the dry dock. When landed on the previously prepared bottom, the interior chambers were to be filled with concrete, the joints between adjoining pontoons, or floating docks, were to be made with tremie-placed concrete, and the dry dock floor and side-walls completed to design lines after unwatering. It is unnecessary to state

* Brooklyn, N. Y.

Mr. Cox. that this plan would have involved great expense, a nice preparation of the bottom under difficulties, and the expenditure of much care and skill in the placing of the floating dock units.

In order to explain the second scheme, it is necessary to review briefly the conditions as known at that time. As stated by the author, the first attempt to unwater occurred about May 1st, 1911. This is fully described in the paper, and it will be recalled that the water level was reduced 16 ft. before evidence of bottom upheaval was observed, and, during attempts to unwater beyond this point, the bottom of the excavation was not ruptured. These circumstances led to the belief that if that particular section was typical of the entire area of

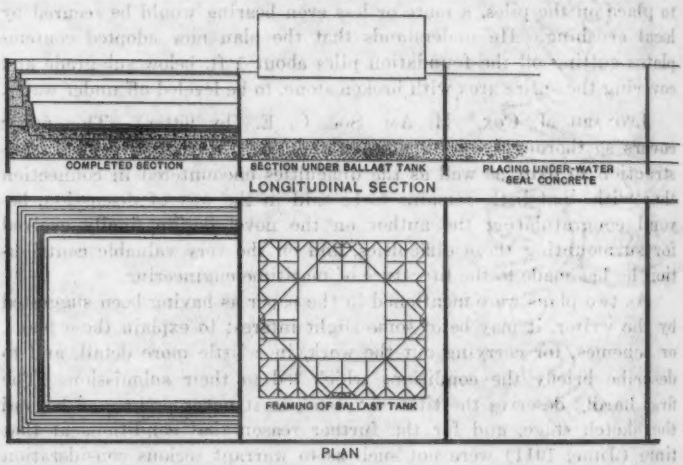

FIG. 22.

excavation floor, there existed below the dock prism a more or less impervious layer of such a thickness that its weight was equivalent to that of 16 ft. of water, a conclusion which was concurred in by the contractor's engineer.

As both the contractor's engineer and the Government engineer believed, from their experience on the work, that it was possible to drive piles 35 ft. into the underlying material, an agreement was reached by which additional compensation was provided for placing piles throughout the bottom, these piles to pierce the impervious layer on which the dock was to rest and pin into the material beneath. The notched heads of the piles were to project 4 ft. into the floor concrete, and the contractor was to be allowed to place not more than 8 ft. of sealing concrete by the under-water method. It was believed

that the anchorage value of the length of piling which would penetrate the material underlying the impervious layer, together with the weight of under-water-placed concrete and that of the impervious layer itself, would safely counterbalance the hydrostatic pressure which would exist when the excavation was unwatered. As a matter of fact, however, it was found to be impracticable, if not impossible, to drive piles of this length. Those driven in Section II, averaged a penetration of 21½ ft., with minimum penetrations as low as 7 ft., giving no anchorage value below the impervious layer. In this same section the concrete seal averaged 6½ ft. with a minimum of 3 ft. Of the entire section area, 55% contained piles which barely penetrated the assumed 19 ft. of impermeable material. Mr. Cox.

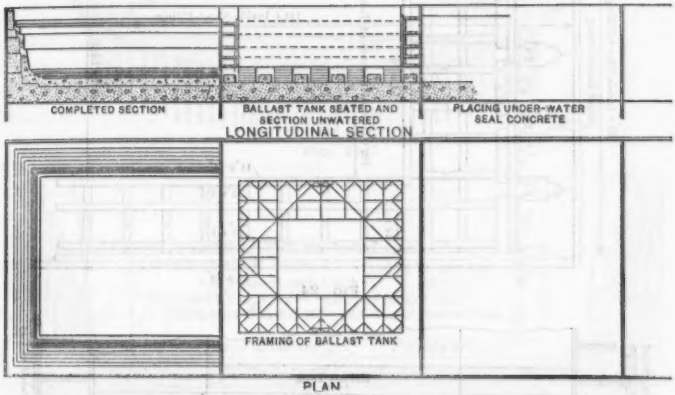

FIG. 23.

The writer was called in consultation in connection with the renewed studies and investigations following the second failure to dewater in February, 1913. Assuming that the failure was due to a lack of anchorage which prevented the unwatering of the partly completed sections necessary for the completion of the dock in the dry, and agreeing fully with the opinions of Mr. Noble and Mr. Harris in regard to the impracticability of using stone ballast, he devised a method of construction involving the use of water ballast. This method, he believed, and still believes, would have insured the completion of the dock by the original design, modified only by comparatively insignificant increases in the quantity of concrete involved and by the addition of certain reinforcing steel to compensate for the lost holding-down power due to short piles. He further believed that the adoption of such a plan would go far toward eliminating the risk of the original crib method, and would expedite completion.

Mr. Cox. In its details, the plan proposed no change in the contractor's bulk-headed sections, or in the preparation of his foundation by the driving of piles to the greatest penetrations possible to obtain. The heads of these piles, as called for in the original contract, were to be embedded

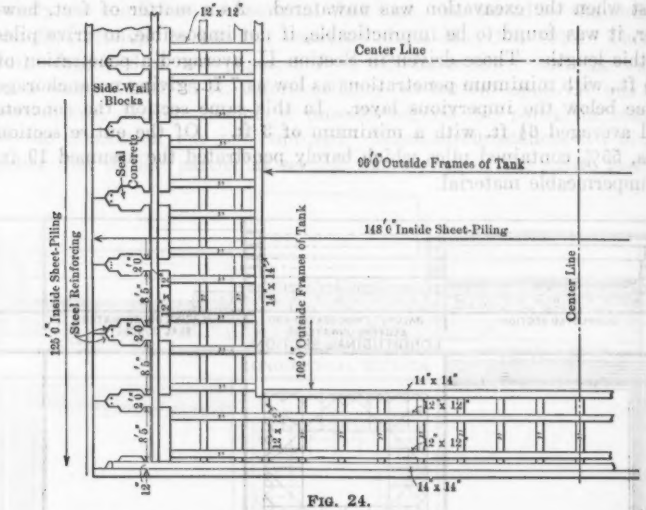

FIG. 24.

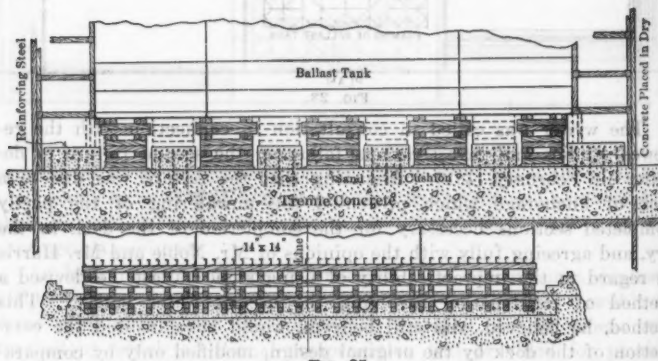

FIG. 25.

in from 11 to 8 ft. of tremie-placed concrete, as shown in Fig. 27. This under-water concrete was to be roughly surfaced at the sides for the reception of pre-moulded concrete blocks of large size. The blocks are shown in section in Fig. 27, and in plan in Fig. 24. They were to

be placed by the 150-ton floating crane already provided for the Pearl Harbor Station. After the piles, tremie concrete, and side-blocks were in place, a steel ballast tank was to be floated into position and sunk by the admission of water to a bearing on timber or metal keel-blocks arranged by divers across the dock section. Then, by pumping, the level of the water in the ballast tank was to be raised some 8 or 10 ft. above the level of the water in the excavation. With the tank resting on the under-water-placed floor, the next step in the operation

Mr. Cox.

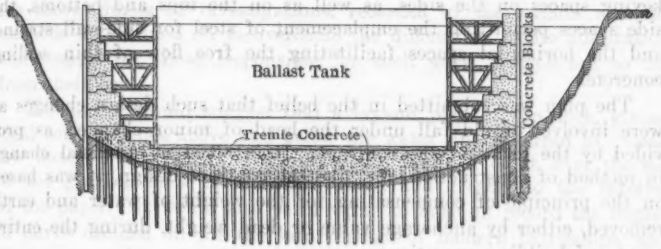

FIG. 26.

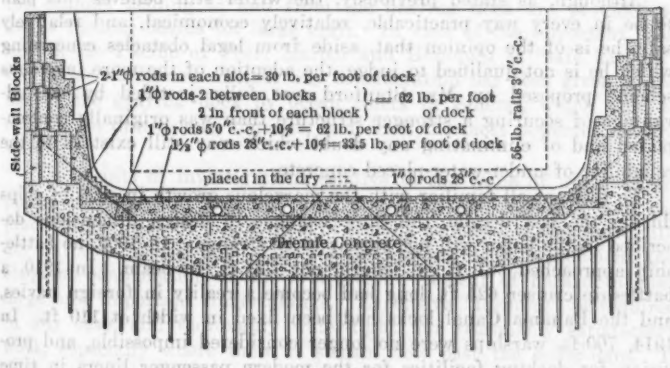

FIG. 27.

involved the unwatering of the space between the section bulkheads and the tank, shoring from the bulkheads or side-wall blocks to the tank sides as the pumping progressed. On the completion of pumping, the floor strips between the keel-block rows were to be completed in the dry, as shown in Fig. 25. The keel-blocks would then be shifted to these completed strips or ribs, and the space thus vacated completed in the same manner. The lower tier of shores between the ballast tank and the side-wall blocks was then to be removed, and the lining of the side-walls was to be placed, working from bottom to top. With

Mr. Cox. the entire section completed as described, water was to be admitted; then the ballast tank was to be pumped to light draft and floated over a shallow cut in the athwartship sheet-piling bulkhead to the next section, where the operations were to be repeated. The entire operation is illustrated in Figs. 22 to 27, from which it will be seen that ample provision was made for bonding the tremie concrete and that placed in the dry; also, that horizontal steel was introduced at the top of the floor-slab. The side-wall blocks were provided with female keying spaces on the sides, as well as on the tops and bottoms, the side spaces permitting the emplacement of steel for side-wall strains, and the horizontal spaces facilitating the free flow of thin sealing concrete.

The plan was submitted in the belief that such design changes as were involved would fall under the head of minor changes, as provided by the terms of the contract. It involved no essential change in method of construction, for, like the contract design, it was based on the principle of compensating for the weight of water and earth removed, either by anchorage value or dead weight, during the entire course of building operations.

Although, as stated previously, the writer still believes this plan to be in every way practicable, relatively economical, and relatively safe, he is of the opinion that, aside from legal obstacles concerning which he is not qualified to judge, the adoption of the more ingenious scheme proposed by Mr. Stanford was fully justified by the advantage of securing a stronger structure than was originally contemplated and of eliminating any doubt which may still exist as to the reliability of under-water-placed concrete.

To those at all familiar with the marvelous growth in sizes of ships during the last decade, the three changes in design dimensions described in the paper will not appear to be strange. In 1909, no battleship approached 581 ft. in length, nor 100 ft. in beam. In 1910, a battleship cruiser 625 ft. long had become a reality in foreign navies, and the Panama Canal locks had been fixed in width at 110 ft. In 1914, 700-ft. warships were no longer considered impossible, and provision for docking facilities for the modern passenger liners in time of war had become a real necessity. At the date of writing this discussion, battle cruisers 800 ft. long and of 100 ft. beam are seriously considered. The Department is to be congratulated on its broad policy of progress and on its determination to keep pace with the advances in every branch of science or art relating to its work.

Mr. Pretty. W. H. PRETTY,* ESQ. (by letter).—This paper, on perusal, conveys the impression of a vast piece of engineering research, from which the engineering world in general may read and learn. The plain

* Peterborough, Ont., Canada.

statement of difficulties met and to be overcome almost disarms criticism, and the determination to carry out the original scheme of building a graving dock in the face of such difficulties, was heroic. The writer's first impression, after reading the paper, was that the position is ideal for a floating dock in preference to a graving dock. The author, however, has already dealt definitely with this question, and no further reference is necessary. The work in hand is the building of a graving dock under extremely adverse conditions, and the thoroughness of investigations, recorded by the author, and the methods determined on to overcome the difficulties, excite admiration and respect for those responsible for such work, carried out so far from their base. Mr. Pretty.

The writer would suggest that a lay-out plan of the dock, giving local contour lines above and below the water line, referred to "mean low water" (to which it is presumed the depth of 35 ft. over the sill of the graving dock is referred) would add greatly to the interest of the paper. It would also be of value to have on record the degree of curve decided on for the safe passage of modern battleships, and the corresponding speed in knots; and, further, if any portions of the channel leading to and from the graving dock are provided to act as turning basins for large craft. In view of the important position in the Pacific of Pearl Harbor and Honolulu as "safe harbors", the writer would ask whether any consideration has been given to the use of the graving dock by ocean liners in general, which tend to outgrow in dimensions, tonnage, and draft the most powerful modern warships.

The results of investigations relative to the value of under-water-placed concrete by "tremies" are interesting and valuable, and the practical abolition of this method of placing concrete, except for auxiliary purposes, in the final plans for the graving dock, is sufficient and eloquent confirmation of the ever-present element of hazard in such large and important undertakings. Expensive "forming" is required in any case, and thoroughly water-tight, for reasonably satisfactory work, especially where there is stream flow past the coffer-dam. It is, however, a valuable aid for auxiliary purposes, and where the concrete thus placed is extraneous to the structure to be built, such as acting as a bottom seal for coffer-dams or to form a better bedding than the existing bottom provides. In the writer's opinion, a structural steel coffer-dam, with steel-plate shell, the whole of the lower part of which could be left permanently in the structure, would amply repay the first cost, in saving of labor, removing hazard, and in future security, and is an investment of the "safety first" order. The use of the "coffer-dam boat", described by the author, is unique, and suggests many possibilities for analogous use in building other structures and substructures, and the water tanks possess many advantages

Mr. Pretty.

for loading and unloading coffer-dams to meet the exigency of the moment.

The experiments on various concrete mixtures are full of interest, and seem to confirm the superiority of clean silicious sand in making "cement mortars". The writer's experience confirms this, and he is of the opinion that some form of surface chemical action takes place between the colloid silica in solution, in the newly-mixed, moist, cement mortar, and the clean quartz grains, probably in the nature of a process of segregation around these grains, which, when in close proximity, become cemented into a solid mass, improving with age; and when widely separated, or intermingled with other materials not amenable to this action, producing a weak concrete, deteriorating with age. We have instances of analogous segregation in the flints formed in chalk beds and calcareous sandstones; the kernels of the former are frequently pebbles, and occasionally have metallic nuclei of fossil origin. The writer has formed the impression from the latter portion of the paper that the use of silicious sand in making the concrete has been abandoned in the final plans for the dock, and that a form of so-called "puzzolan" mixture has been decided on. It would be interesting to know if the value of the latter for depositing in sea water is as great as generally reputed. Cements are often blamed when the mixing and "forming" are at fault, but there is no doubt, however, that each case must be dealt with on its own merits and from the standpoint of the nature of the water in which the concrete is to be deposited—be it salt, or brackish, or fresh water—and the paper certainly conveys the idea that this has been done in the work described.

It may not be without interest to mention here that the placing of under-water concrete has been reported to have been carried out with special dump scows, the concrete being placed in large, specially made, sail-cloth sacks, or bags, firmly sealed up before dumping on the site. The method has its possibilities, and doubtless its limits, when dealing with large undertakings.

The use of vertical tie-rods in the concrete near the outer faces of the walls is commendable. The writer does not recollect seeing any reference in the paper to the size of individual bars to be used for this vertical reinforcement, but may have overlooked this. Generally speaking, he is of the opinion that vertical ties near the faces of walls subject to hydraulic pressure should be individually of large sectional area with substantial anchorages, in preference to a large number of the usual type of small-section deformed bars, the latter being used merely as auxiliary reinforcement. The usual practice of artificially raising the elastic limit to an "excessive degree" by twisting and other deforming processes should be condemned.

Mr. Pretty.

The final plans, with all their completeness for a successful issue of the work, make one hesitate to make any comment save of appreciation for the thoroughness and ingenuity, combined with unique methods, which they show. The writer, however, would like to ask the author if the possibility of building the side-walls of the graving dock independently, received consideration, placing the dock floor later. This would seem to be, at first sight, a likely solution to the problem, the side-walls being built in alternate sections with coffer-dams, such as indicated by the writer in a previous paragraph, using an adaptation of the detachable coffer-dam boat of the author for the removable upper works, and leaving the lower part of the coffer-dams permanently buried in the concrete, the intermediate sections of the walls being built by the use of overlapping coffer-dams, checks being left in the base of the inner face of each side-wall into which the dock floor would lock. The dock floor would be laid in sections of convenient size, similarly, the ends of the coffer-dams in this case sealing with the inner faces of the side-walls of the dock. The tremie concrete in all cases acting as a seal only, would enable the actual true concrete of the structure to be placed in the dry, as indicated by Fig. 28.

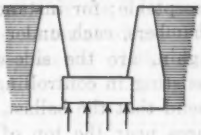

FIG. 28.

The adoption of main centrifugal pump units with vertical shafts, each direct-connected to a three-phase motor, forms an acceptable main pumping plant for a graving dock, where a shore or floating power station is available, and, as similar pumping installations have been already constructed elsewhere, it would be interesting to know if the 2 200-volt motors have proved all that can be desired under the trying conditions of pumping against varying heads, stopping and starting, to meet shoring requirements, etc., in the operation of a graving dock. At first sight, the writer would prefer 550-volt motors, reducing the size of the units, if necessary, and using more of them. Under the latter conditions, it should be possible, with three-phase motors, having suitable resistances in the rotor windings, connected up to the necessary controllers, etc., to have sufficient speed variation available to enable the motors to give out full brake horse power (approximately) throughout the whole period of pumping. The efficiency, from an electrical standpoint, might not be ideal, but it would have many practical advantages. It should not be forgotten, when considering the efficiency from a theoretical standpoint, that the pumps and motors may be idle for intervals extending into periods of weeks and months.

The reference to Artesian pressure and the tests carried out, make interesting reading, bringing to mind our school days and the teacher's

Mr. Pretty.

demonstration of the relative density of salt water and fresh water, in its application to engineering problems of to-day. Coming to the question of earth resistance vertically to loads placed on its surface, generally speaking, it may be taken that the average earth resistance over a large surface per unit area is greater than that obtained by tests made on relatively small isolated areas on the same site. In driving piles in "mud bottoms", it should not be forgotten that in such bottoms the hydrostatic uplift must be referred to the "lower ends of the piles themselves". A case came under the writer's observation some years ago where a large store shed (the floor of which was a concrete cap to a pile foundation in a mud bottom) rose 8 in. or more less than 2 years after the completion of the building. The site was on the marshes at the mouth of a river where the mud deposit was wet and of great depth. The rising was irregular, and the brick walls cracked in several places.

The idea of using a floating dock for the section bases speaks for itself, and deserves none the less credit on this account. A little more information about the timber floating dock to be used would be acceptable; for instance, are each of the five pontoons subdivided into chambers, each under independent control during docking operations? Again, are the side-walls also to act as independent pontoons for assisting in controlling docking operations? The writer would recommend that the ballast, which is to be placed on brackets on the inner faces near the top of the side-walls, be enclosed and under control, if such ballast is really necessary. There is nothing worse than moving ballast in the event of accidental heeling over from any cause whatever, whether the ballast is solid or fluid. To the writer it seems a pity that an appropriation was not secured for making this a small up-to-date floating dock of steel throughout, as it would prove a valuable auxiliary unit for use in Pearl Harbor and Honolulu after completing its work on the Pearl Harbor Graving Dock, for, in addition to its use as a floating dry dock for small craft, it would make a magnificent floating repair yard for ships in open water. It could also act as a floating power station and for salvage purposes, etc.

The use of structural-steel built-up frames, for embedding in the concrete of the bases, is a masterly solution of the problem of dealing with the dock floor, and forms a ready means of attaching stiffeners, etc., for the side-walls. The flat bottom adopted in the final plans for the graving dock is unquestionably the best for such a location and under such conditions as exist there. In the blasting operations carried out for the bottom bedding, is it not possible that the blasting charges may be too heavy? Smaller charges and more of them are better for foundations, as large charges disturb the bottom excavation very severely and very irregularly. The excess of weight of dock of

12 840 lb. per lin. ft. over hydrostatic pressure, referred to base of dock, does not appear to be very large, being apparently only about 2% excess per unit area of bottom of dock; this excess might be increased with advantage to stability. Mr. Pretty.

Concrete loaded with scrap structural-steel sections and punchings, etc., is occasionally useful, and particularly where a reduction in volume for a given weight is absolutely necessary, as occasionally happens in counterweights, etc. Blocks of such loaded concrete have been used by the writer, and, from actual measurements and weighing after manufacture and drying out, and where the concrete was apparently loaded to capacity with scrap metal as stated, the weight came out very approximately at 210 lb. per cu. ft. The use of such concrete in large quantities, however, would prove rather expensive.

Taking the condition of a heavier-than-water structure, it will be interesting to see the balance sheet of weights, and buoyancy, and the resultant "negative buoyancy" (resultant downward pressure) to the credit of the material of the dock, referred to the case where the dock is empty.

Considering, for the moment, the dock as a floating structure, with sealed ends, and "empty": let the volume of material of the dock $= V'$ and its average density $= \rho'$; the volume of the material of the dock below water line $= B$; and the volume of the material of the dock above water line $= C$.

$$\text{Then } V' = B + C \quad \ldots\ldots(1)$$

Let the volume of the empty space inside the dock "below" the water line equal A, and the total volume of fluid displaced equal V and its density equal ρ.

$$\text{Then } V = A + B \quad \ldots\ldots(2)$$

$$\text{and, } (A + B)\,\rho = (B + C)\,\rho' \quad \ldots\ldots(3)$$

$$\text{or, } A = V'\frac{\rho'}{\rho} - B = V'\left(\frac{\rho'}{\rho} - 1\right) + C \quad \ldots\ldots(4)$$

If we take $\Delta\rho'$ as the allowance for resultant downward pressure, then

$$A = V'\left(\frac{\rho' - \Delta\rho'}{\rho}\right) - B = \left(\frac{V'\rho'}{\rho} - B\right) - \frac{V'\Delta\rho'}{\rho} \quad \ldots\ldots(5)$$

$$\text{or, } A = V'\left(\frac{\rho' - \Delta\rho'}{\rho} - 1\right) + C$$

$$= \left\{V'\left(\frac{\rho'}{\rho} - 1\right) + C\right\} - \frac{V'\Delta\rho'}{\rho} \quad \ldots\ldots(6)$$

These equations are suggestive of useful approximations for mental checking as the work proceeds, both in design and construction.

Mr. Pretty. The writer takes this opportunity of thanking the author for bringing to his notice a paper of such unusual interest and wherein the difficulties met have been stated so frankly. It is, indeed, doubtful if any preliminary plans, without the experiences recorded, would have warranted such expensive methods of construction as those indicated in the final plans. To the professional onlooker, it represents a battle with natural forces in the cause of human progress, and one can only wish every success in the final results.

Mr. Baterden. J. R. Baterden,* Esq. (by letter).—This is one of the most interesting papers written on such a subject. In Great Britain we are apt to be afraid to put forth records of a work which has not been wholly successful, but, as the writer has pointed out more than once, the record of one failure teaches us more than many successes, as it enables us to provide against a similar failure in the future.

It is seldom that an engineer has to undertake the building of a dry dock in such a depth of water and in such bad ground as in this case, and the paper opens up so many questions and gives so many details that it is difficult to make useful remarks on it.

The writer has not much faith in concrete deposited under water as a successful method of forming the foundation of the floor of a dry dock, especially with such heavy hydrostatic pressure as in the present instance. A large proportion of the concrete deposited by the tremie method (as the writer would expect) was not water-tight, and some of it was "generally of poor quality". The author toward the end of his paper agrees as to the want of certainty of good water-tight concrete being deposited under water. One of the risks of depositing concrete by the tremie or similar methods is that the heavier particles of the mixture tend to settle in the bottom, and, unless divers are employed, there is no opportunity of having the mortar thoroughly mixed with the stone, and thus consolidated, as in ordinary open work. The consequence is that in many cases a heap of stones accumulates with little or no mortar surrounding them. Where, as in this case, it was found necessary to deposit concrete in this manner, a richer mortar and of larger volume than is customary in ordinary work should be used.

The writer's experience in the use of "plums" in concrete for dry dock work has not been satisfactory. Theoretically, they are all right, but his difficulty has always been to ensure that the "plums" are satisfactorily placed. As long as they are completely surrounded by a sufficient thickness of water-tight mortar, the work is quite satisfactory, but the difficulty is to get this regulation adhered to. Even with the strictest supervision there is a risk of a heap of stones being deposited—for, of course, it is to the contractor's advantage to get

* Newcastle-on-Tyne, England.

Mr. Baterden.

as many "plums" in the work as possible—or of their settling close together and not having sufficient mortar around them, thus forming a sieve for water to penetrate. The extra weight given to the concrete by their use is very little; the saving of cost is certainly appreciable. Where "plums" are used, the stone ingredients of the mixture should not be more than would go through a sieve of, say, from 1 to 1½ in. square.

The writer quite agrees with the author's statement that mortar mixtures for water-tight concrete should be not more than 1 part of cement to 2 parts of sand. This produces a volume of about 2.1, so that the volume of ingredients for the concrete, allowing 45% for voids, should not be more than 3½, which will allow a safe margin of mortar to fill the interstices and surround the stones; if he had a Government behind him, the writer would feel inclined to make the proportion of broken stone only 3, thus ensuring a harder and more water-tight concrete.

It would appear, from the revised plans, that the idea of an intermediate caisson has been abandoned; this arrangement, in the writer's experience, has not been worth the extra cost.

It is a question whether a dry dock, 1 000 ft. long, is required in such a location. It is very unlikely that such a length will ever be required for Admiralty purposes; and, although it is true that the Panama locks are more than 1 000 ft. long, their case is different, as they provide for allowing two or possibly four of the present-day large vessels to pass through at the same time, as well as for the extreme length and beam of ships of the future. The 1 000-ft. ships of the future will be comparatively few, and every 50 ft. of shortening of dock, in ground such as that at Pearl Harbor, means a considerable saving.

The particulars given of bearing power and adhesion of piles in the ground are very interesting. As an instance of the weights which piles will carry, even in very soft ground, the writer, many years ago, supervised the test on four piles, 3 ft. from center to center, driven 25 ft. into the ground, and having on top a platform 6 ft. square to carry the load. The foundation at this place consisted of soft mud and muddy sand for a depth of about 180 ft. A load of 72 tons was placed on the platform, 18 tons per pile, which was much more than the piles in the adjoining ground were to carry. The following was the total settlement of each of the four piles, 6 days after the load had been placed on the platform: 1.08 in., 1.32 in., 3.96 in., and 3.12 in.

The greatest loading test on a single pile, of which the writer is aware, was one supervised by himself more than 20 years ago to test the ground for a battleship berth. The pile was of sawn pitch pine, 42 ft. long, about 12 in. square, and driven 37 ft. into the ground, which consisted of clays of varying degrees of stiffness, finishing in

Mr. Baterden.

a soft leafy clay. The weight of the hammer used was 5 600 lb., its fall was 5 ft., and the finishing sets were ¾ in. This pile actually carried 97 tons before commencing to sink, and then sank quickly and steadily.

It is a moot point whether piling is necessary as a foundation for a concrete dry dock, even in soft ground. The writer has had experience in dry dock construction in the worst of ground, where no piles were used, and the result was quite satisfactory. His experience with the jet process of pile sinking in mixed ground has been much the same as that of the author, and he believes it is only satisfactory where the subsoil is wholly in sand or fine material of a uniform character.

The new designs and method of carrying out the work might be called heroic, and appear to have been carefully thought out. The straight girder, as decided on, is certainly the best. Whatever slight advantages might be gained in strength by the arched form, and the lesser quantity of concrete required, would be more than counterbalanced by the almost impossibility of getting the required curved profile dredged accurately in such a depth of water. The writer hopes, and quite believes, that the work will be brought to a satisfactory conclusion.

Mr. Bellamy.

HERBERT E. BELLAMY,* ASSOC. M. AM. SOC. C. E. (by letter).—This admirable paper is most interesting, and is certain to hold the attention of a very large number of the members of the Society, as all are hoping for the successful solution of the manifold difficulties and problems which the construction of the Pearl Harbor Dry Dock has involved.

To the mind of the colonial engineer, the question of a dry dock of the floating type for economy naturally presents itself; but it would be useless to consider this point further, as the author specifically states:

"All questions as to the type of dock to be provided are in this case beyond discussion, inasmuch as the Congressional authorization for the work distinctly directs the construction of 'one graving dry dock'."

It is hoped, however, that the author will supply additional information on the subject that he has submitted for discussion, namely, the dredging operations, completed in 1912, connecting the harbor with the sea, as described under the heading "Location". It is stated that these operations required the removal of 4 645 000 cu. yd. of material, throughout a channel 5 miles long, at a cost of $3 296 000. It would be of very great interest to know the type, size, and number of dredges used, the method of working, delays, etc., and full particulars while the dredges were engaged over the entrance bar where there was a heavy sea swell at all times.

* Melbourne, Victoria, Australia.

The progress of the works under discussion will be closely followed, especially by engineers resident in Australia, in which country extensive naval works are in contemplation. Mr. Bellamy.

B. C. LAWS,* ESQ. (by letter).—The writer regrets being unable to enter into a technical analysis of this interesting paper, although he has been able to peruse it sufficiently to realize the great instructive value it must have for all engineers concerned with work of this type, who may have the opportunity to read it. Mr. Laws.

The temporary setback, due to the collapse of the coffer-dam on February 17th, cannot but have had a depressing effect on those engaged in the design and construction of the dock, but such an interruption to work, unpleasant as it undoubtedly is at the time, is often a blessing in disguise; it sets us thinking, and frequently new problems or new phases of the old problem, which otherwise would have remained latent, are evolved, the solution of which has a usefulness and application which reaches beyond the work in hand.

Congratulations should be extended to the author and those associated with him, who, after careful and exhaustive analysis of all the factors in the case, have arrived at a course of procedure which bids fair to terminate with great success.

EDWARD BOX,† ESQ. (by letter).—The writer has been much interested in this very lucid description of the attempted construction of a graving dock at Pearl Harbor. Mr. Box.

Whether one regards the undertaking as a reasonable attempt to "direct the great sources of power in Nature for the use and convenience of man", or as a badly conceived scheme which disregarded the laws of Nature, one cannot but admire the very candid way in which the subject has been presented in this paper which should be of estimable value to the student of engineering, and a contribution of more than ordinary value to the world's records of engineering works.

After reading the carefully prepared description of the locality in general, coupled with the particular nature of the site, one cannot help but ask, how was the decision arrived at, which caused Congress, in May, 1908, to specify particularly a graving dock?

As a representative of Great Britain, the writer had the honor of reporting to the International Congress of Navigation, held at Philadelphia in 1912. The subject assigned to him was "Means for Docking and Repairing Vessels". As he then discussed the relative merits of the two systems of dry docks in vogue, *viz.*, graving docks and floating docks, it is not necessary at this time to repeat the views then expressed. Those who are sufficiently interested in this subject will be familiar no doubt with the papers read before that Congress. The

* Hull, England.

† Newcastle-on-Tyne, England.

Mr. Box. writer, however, will only repeat here that it is generally recognized that there are two equally efficient methods of laying dry, for painting and repairing purposes, the larger types of ships, whether they are ships of war or of commerce, *viz.*, the graving dock and the floating dock.

The site, as described in the paper, is one which seems particularly to favor the adoption of the floating dock. The author discusses the question as to choice of type of dock by reference to the Congressional authorization for a graving dock, but Congress went further than that in its instructions, by limiting the cost to $2 000 000, and one becomes interested to know how that amount was arrived at, and to ask whether a graving dock would have been insisted on, had it been known that there was likely to have been so much uncertainty in the cost of its construction.

If, however, we regard the undertaking purely from the point of view of an engineering problem to be achieved at all costs, as we are asked to, the relative merits of the two kinds of docks becomes a separate question, although none the less an important one, and the only feature that remains for discussion, is how to obtain the end in view. The past history has been a chapter of failure for the reason that the difficulties of the undertaking—the writer thinks there can be no doubt about it—were not properly realized when the method of construction was decided on.

In a case, some years ago, where a project was under consideration for a Government graving dock on the Atlantic Coast, under conditions somewhat similar to those at Pearl Harbor, the writer was interested in the preparation of the estimates. The estimated cost was more than $5 000 000. The figures were based on harbor work prices, and, therefore, were probably fairly reliable. This estimate was for a dock considerably less in dimensions than that being built at Pearl Harbor. The project was abandoned, and a floating dock was constructed at much less cost.

As an engineer, the writer has long cherished the desire to build a dock on a site presenting difficulties such that the usual methods of construction would no longer suffice. He has never known a case, however—although there may have been one—such as Pearl Harbor presents, where a graving dock has been attempted. What he has had in mind is a modified design for a floating dock to be sunk on a dredged site and then converted into a concrete graving dock by sectional treatment.

To his mind, a structure complete within itself, although built first in sections, sunk into place, and then treated sectionally, is the preferable method, where practicable, of dealing with a problem such as Pearl Harbor would appear to present. In this way the question of compressibility is practically eliminated, and equal loading throughout is obtained.

Mr. Box.

With regard to depositing concrete, the best concrete obtainable is that which is deposited in the dry and flooded on initial set. In graving dock work, the writer never uses concrete of less strength than 5½ to 1 of cement, which would be considered a weak mixture in the present case. The proportion of sand to ballast, of course, depends on the grading of the particular materials used.

The site for the Pearl Harbor Dock has been badly tampered with and, for this reason alone, whatever method is adopted, further difficulties must of course be expected, the worst feature of which appears to be the piling of the ground. With the necessary funds, tenacity of purpose, and under the guidance of practical engineers of matured experience, it is possible that some day the Pearl Harbor Dry Dock will be an accomplished fact.

The writer cannot close his remarks without expressing sympathy—a sentiment almost unknown with reference to engineering work—with those who have been laboring so hopelessly for years on what must have been regarded by many as an impossible task.

Mr. Stanford.

H. R. STANFORD,* M. AM. SOC. C. E. (by letter).—The writer is extremely grateful to those who have been interested enough to discuss his paper, and extends to them his thanks and appreciation.

No attempt will be made in this closing discussion to consider any remarks or opinions, expressed in preceding discussions, which are controversial in character, inasmuch as the paper only purports to be a record of facts and conditions. Careful effort will be made, however, to answer all questions which have been raised, and to supply the additional data or information requested.

In reply to questions raised by Mr. Taft, it may be stated that dilution with fresh water of the sea water contained within the cofferdams, in order to reduce the saline content and to avoid the deleterious effects of salt water on freshly placed concrete, was considered, but the idea was necessarily abandoned because of the limited supply of fresh water.

Experimental cubes of tremie-placed concrete, measuring 6 ft. on the side, were made with one brand of German cement and two brands of American cement, in order to determine, if possible, whether the use of a special brand of cement for tremie concrete would be warranted. These experiments indicated that "Santa Cruz" cement, which had been approved for the work, gave results as good as those obtained with the other test cements, and that the kind of cement which had been used was not chargeable with the trouble experienced with the tremie concrete.

The cement approved for use in the dock is the "Santa Cruz" brand, made at Davenport, Cal., subject to the standard Navy Depart-

* Philadelphia, Pa.

Mr. Stanford.

ment specifications, from which the following, relative to chemical requirements, is quoted:

"The cement shall be the product obtained by finely pulverizing clinker produced by calcining to incipient fusion an intimate mixture of properly proportioned argillaceous and calcareous substances, with only such additions subsequent to calcination as may be necessary to control certain properties. Such additions shall not exceed 3% by weight of the calcined product.

"In the finished cement, the following limits shall not be exceeded:

"Loss on ignition for 15 min.....4.00%
Insoluble residue.....1.00%
Sulphuric anhydride (SO_3).....1.75%
Magnesia (MgO).....4.00%"

The importance of the proper mechanical mixing of the concrete in a batch is fully recognized, and steps have been taken to insure that there shall be no failure in this respect due to mixing for too brief a period or at too rapid a rate.

The experimental investigations in the use of tremies, which were conducted in connection with this work, did not give much consideration to methods of freeing the tremie from water when it was being charged at first. This apparent neglect was due to the fact that the straw pillow or plunger inserted in the tremie when the process was started practically prevented the salt water from entering all but the very first portion of the concrete charge and this part of the concrete, under any circumstances, would necessarily become impregnated with salt water when issuing from the tremie to begin the filling of the form. The straw pillow remained in the bottom of the form and was so compressed as to be unobjectionable under these conditions; an elaborate or expensive plunger was not considered justified.

In reply to a question by Mr. Pretty: a contour survey of the dock site, made before construction work was started, showed that the surface of the ground sloped quite uniformly from an elevation of approximately 14 ft. above mean low water at the head of the dock to an elevation approximately 10 ft. below mean low water at the entrance.

For a distance of approximately one mile from the open sea, the entrance channel to the Naval Station is straight, and has been dredged to provide a least width of 600 ft. The remainder of the channel has a least width of 500 ft. in the straight portions, and somewhat greater widths in curves. The minimum radius of the dredged channel is 1 600 ft. The safe speed for deep-draft vessels through this channel is from 4 to 6 knots per hour. There are large areas within the harbor, in the vicinity of the Naval Station, over which the natural depth of water is much in excess of that required by naval vessels, and this rendered the dredging of turning basins unnecessary.

Mr. Stanford.

The history of dry-dock construction in America is apparently much the same as that in other countries. With the authorization of each new large dock, effort was made to anticipate the growth of ships and to make the dock large enough to admit the largest vessel which would probably be built; due to the very rapid increase in the dimensions of ships, however, it has frequently been the case that when the docks were completed, usually after protracted delays from one cause or another, they had actually been outgrown during the period of construction. When dimensions were fixed for the locks of the Panama Canal it was expected that those dimensions would establish limits in the design of new ships for both the naval and merchant services, and, when the dimensions of the Pearl Harbor dock were made to accord with the Panama locks, the designing engineers had satisfaction in the thought that this would be one dock at least which would not be outgrown.

The revised plans do not provide for the use of any imported silicious sand in making concrete for the body of the dock, except for the small quantity of tremie-placed concrete required for making the seals between adjacent sections. It is expected that the rich mixtures specified will result in making a practically impervious concrete which will insure the mass against depreciation from chemical changes and disintegration and will efficiently protect the embedded steel.

The vertical reinforcement rods near the outer vertical faces of the side-walls of the dock are $1\frac{5}{16}$ in. in diameter and 17 ft. long, and are 18 in. apart. The specified range of ultimate tensile strength of these rods is from 55 000 to 70 000 lb. per sq. in., which is a safe limit, without making any allowance for increase resulting from the mechanical process of twisting or deforming. The sectional area of all embedded steel is made heavy as a protection against corrosion losses.

The method of building the side-walls first and then constructing the bottom between the walls was given very careful consideration, but the cost and difficulty in arranging details of construction, which would avoid the necessity for any considerable quantity of under-water placed concrete in building the central portion of the dock, led to the abandonment of the idea.

There are three large naval docks, which have been in operation for some time, each of which is unwatered by four vertical-shaft pumps operated by 2 200-volt motors. No trouble whatsoever has been experienced with these motors, either as a result of the varying head on the pumps, or in starting or stopping the motors. The suggestion that the motors might advantageously be equipped with slip-rings and controllers, in order to obtain a certain degree of speed regulation, is a point well taken; with a 10% control, it is practicable to regulate the power input into the motor so that it will remain almost constant

Mr. Stanford.

during the entire range of pumping, and this is a very material item, considering that the dry-dock load imposes the peak-load condition on the power plant, and that maximum motor efficiency is of little consequence, because of the brief and infrequent intervals of pumping. It has been found in service that four pumps for one dock is a very desirable number, to provide for the regulation of unwatering in docking a ship, and also for break-down service; to increase the number with corresponding reduction in unit capacity would tend to add to the cost of the installation, on account of the expense of their valves and connections.

Each of the five pontoons of the floating dock is divided by a water-tight center bulkhead into two water-tight compartments; each of these compartments is further subdivided by swash bulkheads into four sub-compartments. All pumping is performed from the side-wall compartments, and each pontoon compartment can be pumped from either side-wall.

The small floating dock is being provided by the contractor as an item of plant necessary for the construction of the graving dock. The Navy Department fully recognized the great value which this floating dock would have as a permanent feature of the station's equipment on the completion of the graving dock, but, in view of the difficult and more or less hazardous character of the service which will be performed by the dock for the contractor, it was thought best to make the floating dock specifically an item of plant, in order to avoid the possibility of question as to responsibility in case of trouble.

Great care is being exercised in conducting the dredging operations, and in cutting off the tops of piles to avoid injury to the remaining piling which will form part of the prepared foundation for the dock. If any injury is suffered by this piling, it will be necessary to replace the injured piles with good ones.

The following are the estimated values, per linear foot of dock, of various elements in the completed structure, which will act in the nature of weights or ballast, in addition to the estimated force of 12 840 lb. due to the weight of concrete, to insure a positive downward resistance to flotation or uplift:

(*a*)	Due to the weight and structural moment of the reinforced concrete ties in the surrounding crane track..	1 360 lb.
(*b*)	Weight of soil on the narrow outstanding shelf in the outer face of the side-walls.....	11 160 "
(*c*)	Probable average weight of concrete at 154 lb. per cu. ft., instead of 150 lb.....	14 080 "
(*d*)	Weight of blocking on floor of dock.....	1 800 "
(*e*)	Frictional resistance of earth against side-walls.....	36 000 "
		64 400 lb.

Mr. Stanford.

Referring to the statement of Mr. Baterden that "it is a question whether a dry dock, 1 000 ft. long, is required in such a location", it should be noted that a dock having a lesser length would not comply with an implied requirement of the Act of Congress under which the dock is authorized. This reason is mandatory, aside from any consideration of military need.

The writer is in agreement with Mr. Baterden as regards the necessity, in general, for foundation piling for a concrete dock, even when constructed in soft ground. An essential reason for the great thickness of concrete in the floor of a graving dock, built in a reasonably favorable soil, is that it gives the dock sufficient weight to resist flotation; in other words, the dock weighs little more than the water which it displaces, and therefore imposes on the underlying soil a weight which is only a little more than that of the water which would naturally flood the completed excavation for the dock, and probably much less than that of the soil which was removed in making the excavation, and which in original formation had been safely supported for ages. Under these conditions, and in ordinary cases, there can be little need for piling if the dry dock structure is sufficiently strong to distribute its weight over relatively small soft spots in the bottom of the completed excavation, and the use of piling under such circumstances is in the nature of a precautionary measure or factor of safety.

Dredging for the channel was begun at the outer entrance, in water from 15 to 25 ft. deep, by using a steam lumber schooner fitted with hoppers and equipped with a 14-in. centrifugal pump, connected to a 20-in. suction pipe, and driven by a 275-h.p. steam engine. The suction pipe was rigged from an A-frame forward. This machine handled sand, loose coral, and mud very effectively in shallow water. As the depth became greater and the softer material was removed, a clam-shell dredge, equipped with a 4½-yd., 13-ton bucket, was put into use. This machine handled mixed materials as encountered, but did not remove successfully coral in ledge formation nor partly decomposed lava rock. For excavating these hardest materials a drag-scraper dredge, equipped with a 3-yd. bucket, was used; the bucket was sunk at the greatest possible distance from the dredge, which was moored with anchors, the water being too rough to permit the use of spuds, and was drawn in by a cable rove through a sheave at the stern of the dredge; the bucket was hoisted when a few feet forward of the hull. This dredge operated successfully on the hardest materials, and at the greatest depths, and was especially successful on the clean-up in cuts from 37 to 38 ft. deep, with a minimum of 35 ft.

A 16-in. suction-dredge, without cutter head, and operating from moorings, was used at the inner sections of the work. This dredge did not operate successfully in a seaway, and was used more extensively

Mr. Stanford.

on the less exposed parts. Attempts were made to operate both suction-dredges and a dipper-dredge from spuds in the entrance fairway, but there was always enough swell, even in the stillest weather, to render the use of spuds impracticable.

The dredging of the channel was begun on August 23rd, 1909, and completed on January 30th, 1912. During this period the weather conditions were generally favorable, with no heavy tropical storms, although the dredges were frequently withdrawn to shelter on account of threatening weather. For months at a time the weather was fair, with trade winds springing up at about 10 in the morning and dying away between 4 and 6 in the afternoon. The evenings, nights, and early mornings were usually still. At the outer entrance, due to the trade winds, a fairly heavy swell was running at all times, and, as the deepening progressed, this extended farther and farther into the channel. The hard material in the entrance was broken up by drilling and blasting before cleaning up with the drag-line dredge. After the finished depth was nearly reached, considerable blasting was done without drilling, charges of explosives being placed on submerged boulders or ledges and fired by electricity. These blasts were quite effective, but only over a limited extent, and to a very limited depth.

The questions raised by Mr. Box are very interesting. In stipulating that the dock should be of the graving type, Congress was undoubtedly influenced by the fact that a dock of that type, after being completed, involved practically no expense for repairs and upkeep, whereas those costs for a dock of the floating type, with its mooring and approaches, are continuous and large. Although Congress is apparently willing to appropriate liberally to provide for the first cost of public works improvements, there is great difficulty in obtaining annual appropriations for maintenance and repair. Estimates for new works, therefore, are very apt to be larger than would otherwise be the case, to provide for very permanent and durable construction. As a business proposition, it would frequently be economical, in the long run, to spend less to begin with and a little each year for maintenance, so planning that the interest on the saving in first cost would more than equal the maintenance expense; but, knowing that there will be difficulty in obtaining the maintenance fund, there is a tendency to adopt the more extravagant method.

Floating docks have been found very efficient and satisfactory in the docking of our naval vessels, and there can be no question as to the practicability, value, and usefulness of docks of that type. The writer will frankly concur in the opinions expressed by Mr. Pretty, Mr. Bellamy, and Mr. Box, that the natural depth of water in Pearl Harbor, combined with the unfavorable soil conditions found at the

Naval Station, are strong arguments favoring the selection of the floating rather than the graving dock for that place. Mr. Stanford.

More thorough borings and examination of the ground conditions at the dock site before beginning operations would probably have obviated at least a part of the difficulty and expense which have been incident to the work. Such examinations, together with careful preliminary investigations of the material and labor resources in the vicinity, would also have shown that the first estimate of cost of the dock was quite inadequate. The explanation of the failure to obtain these data lies in the fact that there was a sudden realization of the importance of quickly developing this base, coupled with the altogether too frequent error of laymen in failing to recognize properly the importance and need of the engineer for such service.

Paper No. 1355

THE HYDRAULIC JUMP, IN OPEN-CHANNEL FLOW AT HIGH VELOCITY*

By Karl R. Kennison, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. B. F. Groat, H. B. Muckleston, Frederic P. Stearns, Carl B. Andrews, R. D. Johnson, Mansfield Merriman, E. G. Walker, Edward W. Bush, H. F. Dunham, Robert F. Ewald, L. D. Cornish, Caleb Mills Saville, and Karl R. Kennison.

Synopsis.

This paper presents an analysis of the hydraulics of the turbulent discharge below a spillway dam, where the so-called "jump" frequently occurs. A knowledge of the hydraulic principles involved should enable destructive high velocities and turbulence to be avoided, or intelligently provided for, in the design of flumes, dam foundations, etc.

The arrangement of the paper is as follows:

1.—Introductory.

2.—Conclusions.

The interesting feature is that in every open channel, except at controlling sections where the discharge is a maximum, there is, in addition to the existing water level, another level at which the same quantity of water might be flowing, under the same head. These two "alternative stages" should be recognized in the design of all structures for controlling the flow of water. The hydraulic jump is merely the turbulent passing between these two stages.

* Presented at the meeting of November 3d, 1915.

3.—Mathematical Basis for Conclusions.
(*a*) Relation between Depth, Head, and Discharge.
(*b*) Maximum Discharge at Controlling Section.
4.—Examples of the two Alternative Stages.
5.—Examples of the Hydraulic Jump.
6.—Destructive High Velocity below Spillway Dams.

1.—Introductory.

When water is discharged into a flume through a contracted gateway and under a considerable head, it sometimes continues to move in a thin sheet at a high velocity along the bottom of the flume for several hundred feet. Then it suddenly becomes turbulent and forms what is called a "hydraulic jump", the surface level down stream from this point being much higher than that of the approaching high-velocity discharge; or, when water flows over an ogee dam and out on a smooth apron it sometimes continues in a thin sheet, having a surface level far below the normal level of the river a little farther down stream, until it suddenly changes into a tumbling mass, rising to the normal river level by this "back roll" or "hydraulic jump". An excellent illustration of this is seen in Fig. 1, taken from a photograph, kindly furnished by the United States Reclamation Service, of certain flood conditions over the Granite Reef Dam.

This phenomenon sometimes becomes of great practical importance, and has been investigated mathematically by the writer at the request of John R. Freeman, M. Am. Soc. C. E., because of its interest in connection with the design of two important dams under widely different conditions in different parts of the country. In one of these cases it was desirable that the back roll or hydraulic jump should not be pushed far down stream from the foot of the ogee, off from a concrete apron which protected a clay river bed from scour; in the other case it was desirable that the back roll or hydraulic jump, with its violent surges, should not be pushed down stream so far as to interfere with the draft-tube exits of the power-house.

The problem does not appear to have received proper attention in the textbooks. No exhaustive mathematical analysis is attempted here, but merely an explanation of the peculiar conditions of flow which make the jump possible. The conclusions are as follows:

2.—Conclusions.

In the case of water flowing in an open channel on a steep gradient there are certain controlling sections which throttle the flow and determine the quantity of the discharge, that is, certain points where, for the given head and channel depth, the discharge is a maximum. If the contraction which causes this throttling of the flow is sufficiently gradual—for example, a submerged dam with smooth gradual approach and get-away—it can be shown that the depth of water at this point is theoretically two-thirds of the total head measured from the channel bottom or dam crest up to the hydraulic gradient, and the discharge per foot of length, therefore, should be $3.09\ H^{\frac{3}{2}}$.

At other points than at the controlling sections, however, the depth of water is not necessarily determined by the quantity discharged and the available head, but also by the channel conditions; because, for a given quantity of water flowing and a given head or elevation of hydraulic gradient, there are two possible surface-water levels which we will call alternative stages. The upper stage is the normal level in an ordinary stream, and for very low velocities is practically coincident with the hydraulic gradient. The lower stage is that ordinarily taken by water discharged at high velocity from an orifice or below a spillway dam. This is the more unstable of the two levels, due to the friction of high velocity on the channel bed. In other words, it can be shown that in any open channel, except at controlling sections such as just referred to, there is, in addition to the existing water level, another level at which the same quantity of water might be flowing with equal steadiness and under the same head or elevation of hydraulic gradient.

As these two definite alternative stages are the only possible ones under the existing head for smooth undisturbed flow, the stream must stand at one of these two levels, that is, water flowing in a smooth channel of uniform section must continue to flow at its existing stage, whichever one that happens to be, until, either due to a change in the channel bed or after sufficient loss of head in friction, it encounters a controlling section where the two alternative stages merge into one, and the depth is two-thirds of the total head. Below this controlling section the two possible stages again separate. At such a point as this the water level may change, without disturbance or interruption of the steady flow, from upper to lower stage, or from lower to upper

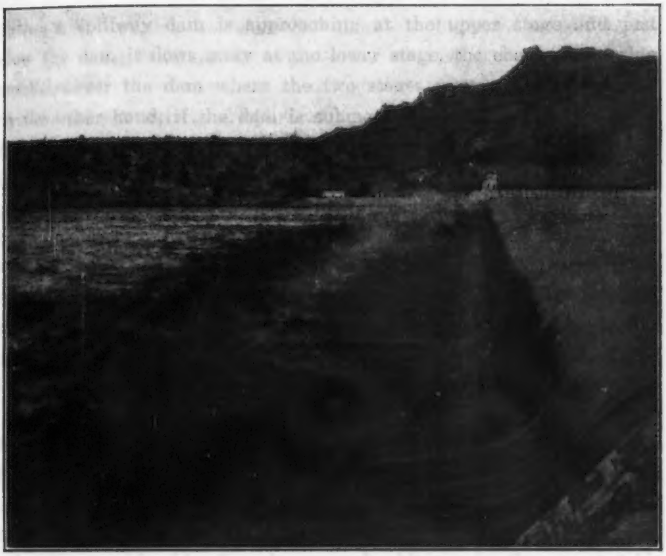

FIG. 1.—THE GRANITE REEF DAM IN ACTION.

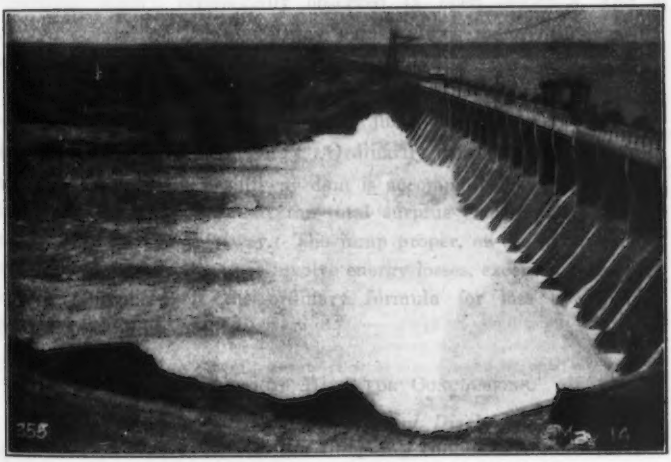

FIG. 2.—THE BASSANO DAM IN ACTION.

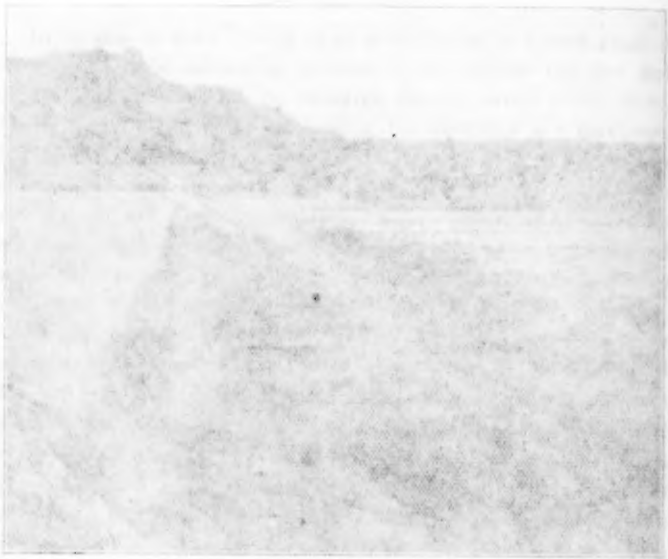

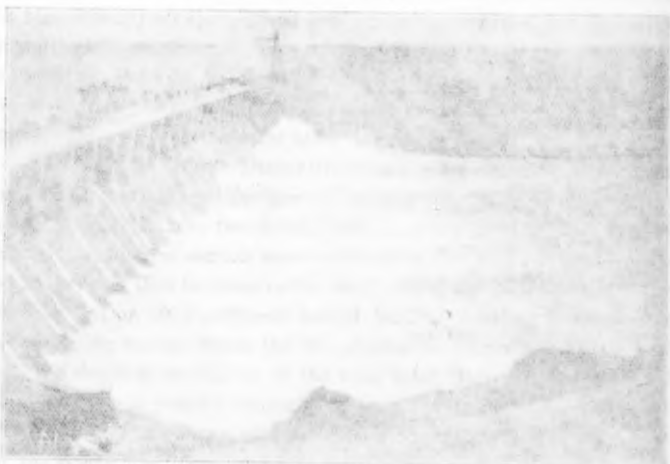

stage, or may continue at the same stage. For example, the water behind a spillway dam is approaching at the upper stage and just below the dam it flows away at the lower stage, the change occurring smoothly over the dam where the two stages were merged into one. On the other hand, if the dam is submerged by back-water almost as high as the up-stream pool, the surface may simply dip down locally at the dam where the depth is two-thirds of the head. In this case the upper alternative stage is maintained throughout, below as well as above the dam. It can also be shown that under certain circumstances the flow over a dam may theoretically be reversed, the dam facing down stream, and the water apparently running up hill—simply a case of passing from the lower to the upper stage smoothly, over a gradual controlling section where the depth is equal to two-thirds of the head.

In such phenomena the presence of the controlling section tends to eliminate any disturbance in passing from one level to the other, so that the existence of the two alternative stages is not noticed; but water flowing at the lower high-velocity stage and suddenly encountering obstructions which tend to destroy its velocity may rise suddenly, and with considerable disturbance and eddying, to the more stable upper low-velocity stage, and this phenomenon is the so-called "hydraulic jump", occasionally observed in open channels, and a common occurrence below spillway dams. It is merely the passing between the two alternative stages.

In this phenomenon the only energy loss is that due to the accompanying disturbance and eddying, the jump proper merely transferring kinetic into potential energy. Ordinarily, however, this hydraulic jump occurring below a spillway dam is accompanied by such violent disturbance and eddying that the total surplus energy in the water may be destroyed in this way. The jump proper, or the passing from lower to upper stage, does not involve energy losses, except incidentally, and it is doubtful if the ordinary formula for loss by "sudden expansion" applies in this case.

3.—Mathematical Basis for Conclusions.

(*a*) *Relation Between Depth, Head, and Discharge.*—The mathematical deductions by which the foregoing conclusions were reached

are presented with the assistance of diagrams and as briefly as possible so as to avoid confusing mathematical details. The careful reader will notice that in some parts of the discussion the variation of velocity at different points in the cross-section of a channel and the variation of the slope of the hydraulic gradient under different conditions of flow, have been neglected. This has been done for the sake of simplicity, and does not affect the general conclusions as to the existence of the two alternative stages or the proposition that the hydraulic jump is not an absorber of energy by "sudden expansion". Referring to Fig. 3, the gradual slope of the hydraulic gradient represents channel friction losses.

H = the total head above the channel bed or distance up to the average hydraulic gradient for all the water in the stream;

d = depth of water;

V = average velocity;

Q = quantity of water discharged per unit width of channel.

This assumption, that we are dealing with a strip of unit width, is made for the sake of simplicity, and the conclusions will not be directly applicable to the full width of the stream unless the form of its cross-section approaches a rectangle.

From the relations, $d + \frac{V^2}{2g} = H$, and $V = \frac{Q}{d}$, we obtain the following general expression or equation giving the relation between depth, d, head, H, and discharge, Q:

$$d^3 - H d^2 + \frac{Q^2}{2g} = 0.$$

Note that this is a cubic equation in d, that is, for a constant head and discharge, there are three roots or three values of the depth, d. One of these comes out negative, leaving two real values corresponding to the two alternative stages, as shown in the following example.

Suppose the head, $H = 10$ ft., and the discharge, $Q = 50$ cu. ft. per sec. The general equation then becomes $d^3 - 10d^2 + 38.8 = 0$. Solving,* $d = 9.58$, 2.24, or -1.82. The last root, being negative, is

* The writer has never seen a formula arranged to give directly the three roots of any cubic equation. Hence the following is presented in the hope that others may find it useful:

If $x^3 + Ax^2 + Bx + C = 0$

$$x = \frac{2}{3}\left(+\sqrt{A^2 - 3B}\right)\cos.\frac{1}{3}\cos.^{-1}\frac{9AB - 2A^3 - 27C}{2\left(+\sqrt{A^2 - 3B}\right)^3} - \frac{A}{3}.$$

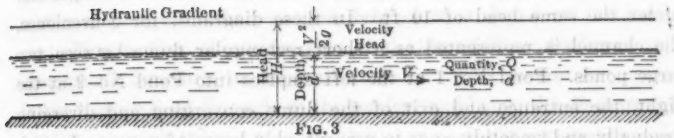

FIG. 3

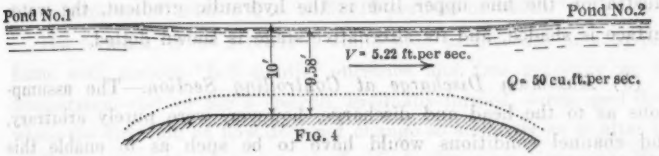

FIG. 4

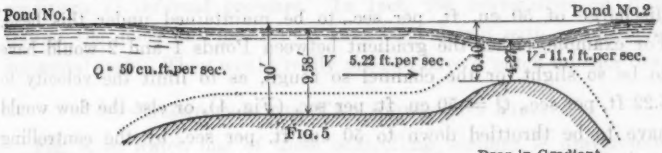

FIG. 5

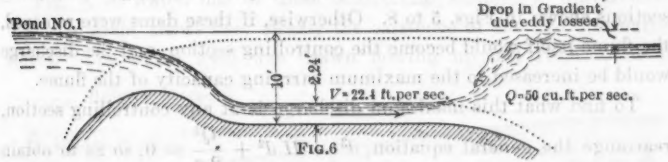

FIG. 6

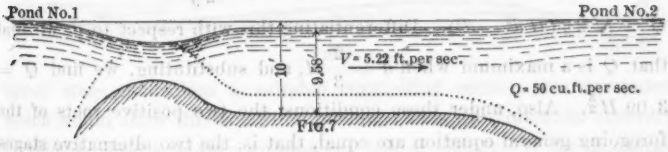

FIG. 7

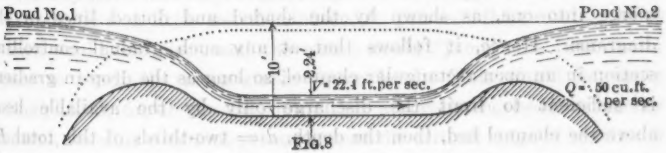

FIG. 8

unreal, and the two alternative stages correspond to depths of 9.58 and 2.24 ft., respectively. This condition is shown in Figs. 4 to 8, in which 50 cu. ft. per sec. are discharged at either of the two stages and under the same head of 10 ft. In these diagrams, for convenience, the channel is represented as a short rectangular flume between two large ponds. Pond No. 1 at the left empties into Pond No. 2 at the right, the entrance and exit of the flume converging and diverging gradually and smoothly so as to prevent eddy losses of energy. In each illustration the fine upper line is the hydraulic gradient, the water surface is shaded, and its alternative stage is shown dotted.

(*b*) *Maximum Discharge at Controlling Section.*—The assumptions as to the head and discharge, however, were purely arbitrary, and channel conditions would have to be such as to enable this discharge of 50 cu. ft. per sec. to be maintained under this head. For example, either the gradient between Ponds 1 and 2 would have to be so slight, or the channel so rough, as to limit the velocity to 5.22 ft. per sec., $Q = 50$ cu. ft. per sec. (Fig. 4), or else the flow would have to be throttled down to 50 cu. ft. per sec. by the controlling sections shown in Figs. 5 to 8. Otherwise, if these dams were removed, the flume itself would become the controlling section, and the discharge would be increased to the maximum carrying capacity of the flume.

To find what this maximum discharge is at any controlling section, rearrange the general equation, $d^3 - H\,d^2 + \frac{Q^2}{2\,g} = 0$, so as to obtain $Q = \sqrt{2\,g\,(H\,d^2 - d^3)}$. Differentiating this with respect to d, we find that Q is a maximum when $d = \frac{2}{3}\,H$, and substituting, we find $Q = 3.09\,H^{\frac{5}{2}}$. Also, under these conditions, the two positive roots of the foregoing general equation are equal, that is, the two alternative stages merge into one, as shown by the shaded and dotted lines in the diagrams. Hence, it follows that at any such gradual controlling section in an open rectangular channel, so long as the drop in gradient is sufficient to limit the discharge only by the available head above the channel bed, then the depth, $d =$ two-thirds of this total H, measured above the channel bed, and the discharge Q equals $3.09\,H^{\frac{5}{2}}$.

This is hardly to be taken as a practical formula for actual weir discharge, as the general equation for open-channel flow, on which it

is based, assumes that the pressure gradient coincides with the water surface, or that the water in every part of the section is under a pressure head equal to the vertical height of water above it. As a matter of fact, on a sharp-crested weir, or on a dam crest, or similar controlling section, the under side of the over-falling discharge is at atmospheric pressure, or approximately so. This means an increase in the velocity head throughout the section, and hence the discharge, Q, will exceed $3.09\ H^{\frac{3}{2}}$ per foot of width. Note that the Francis formula for a sharp-crested weir is $Q = 3.33\ H^{\frac{3}{2}}$ per foot of width.

The formula, $Q = 3.09\ H^{\frac{3}{2}}$, would hold in the case of a by-pass flume with smooth "bell-mouth" entrance and free get-away at the down-stream end, or for a smooth, gradually-formed, submerged dam, where the direction of flow does not change so suddenly as to alter the conditions of internal pressure. In fact, for convenience in illustrating, the dams in Figs. 5 to 8 have been drawn with a contracted horizontal scale. They would really need to have a much broader base.

4.—Examples of the Two Alternative Stages.

Fig. 9, in which one of these controlling sections is drawn more nearly to scale, shows very clearly the existence of the two alternative stages. The water level was drawn flowing up hill from lower to

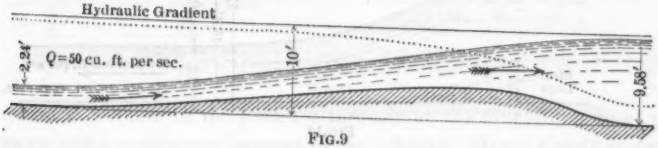

Fig. 9

upper stage, and then a suitable controlling section was computed which would allow this condition of flow. This illustrates the recovery of velocity head smoothly without any loss of energy. If the discharge was reduced to a little less than 50 cu. ft. per sec., the two alternative stages would not meet, and the water would "jump" the intervening space to reach the more stable upper level. This would be easily accomplished, for it can be shown that although the head, or energy content, remains constant, yet at or near the critical stage of maximum discharge, where the depth is equal to two-thirds of the head, the water surface is comparatively uncertain, and is easily subject to considerable fluctuation for very slight inequalities in effective area of

section. This tendency may be noted in a long flume under maximum discharge, such as a flood by-pass flume around a coffer-dam. It has this inherent tendency to surface fluctuations, which should not be aggravated by bends in the flume where it is possible to make the latter perfectly straight.

The existence of the two stages is also brought out in Figs. 6 and 7. Referring to Fig. 6: In case Pond No. 2, into which the flow empties, is low enough—so that, after the friction losses in the flume and all the eddy losses at the flume exit, there is still enough potential energy left to reach the pond level—then conditions will remain as in Fig. 6, with either a definite "hydraulic jump" as shown, or a series of more or less irregular waves, finally reaching the level of Pond No. 2. But if Pond No. 2 is higher than this, that is, so high that it cannot be reached by the total potential energy of the flume discharge, after the necessary friction losses of the high velocity in the flume and eddy losses caused by the jump have been deducted, then the pond will back up into the flume somewhat as shown in Fig. 7.

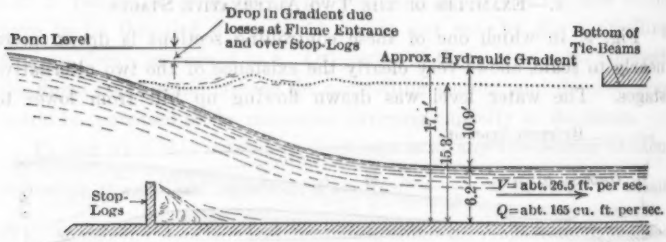

FIG. 10

This is apparently what happened in the case of a flume of the Massachusetts Metropolitan Water-Works, observed and reported by F. P. Stearns, Past-President, Am. Soc. C. E. Fig. 10 is taken from a print showing the measured velocities and surface profile in this flume, 40 ft. wide, emptying a reservoir at the left. The water is apparently flowing at the lower alternative stage, and the corresponding upper alternative stage is shown dotted. Besides what is shown in this figure the print shows the flume extending to the right a total length of 671 ft., with a bend in the middle which caused irregular waves in the down-stream half of the flume. Mr. Stearns states that during a later flood than the one shown here—possibly a greater flood, but only

slightly greater—he visited the flume and found the water at just about the level marked "bottom of tie-beams". Note the coincidence between the upper alternative stage and this point at which Mr. Stearns observed the water surface. Apparently, the discharge was not materially different in the two floods, but in the one case the particular channel conditions maintained the lower alternative stage and in the other the upper alternative stage.

5.—Examples of the Hydraulic Jump.

The gradual throttling of the flow represented in Figs. 5 to 8 permits the discharge to follow along either the lower or upper alternative stage, as shown particularly by comparing Figs. 6 and 7, but, in the case of the ordinary dam crest, the contraction is so sudden that the conditions of internal pressure are affected. The tendency is all

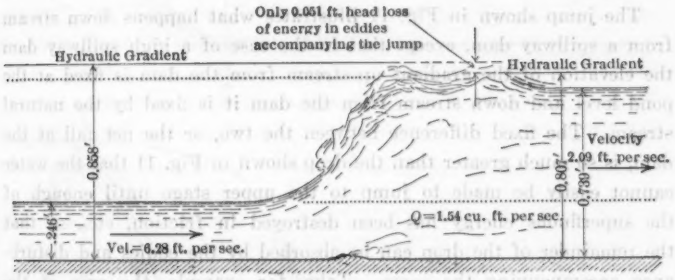

FIG. 11

toward a decrease in the pressure throughout the overfalling sheet of water, and a consequent increase in the velocity. Hence a weir or dam furnishes a velocity-creating condition, and tends to force the water level to drop to the lower or high-velocity stage, where it must continue until it encounters a velocity-destroying and pressure-creating condition, when it will rise again to the more stable upper stage of low velocity.

This rise is shown in Fig. 11, which represents one of four observations of the hydraulic jump by Bidone, quoted by Merriman as follows: The depth before the jump equals 0.246 ft.; the velocity before the jump equals 6.28 ft. per sec.; the depth after the jump equals 0.739 ft.; from these data the other quantities shown in Fig. 11 are easily computed closely enough for our purposes, assuming that the depths

before and after the jump were measured from the same floor line, parallel to the hydraulic gradient. An actual case similar to this, and one which brings out the importance of recognizing the two alternative stages, is illustrated in a recent issue of a technical journal.* A concrete chute, 9 ft. wide and 5 ft. high, at the end of the Truckee Main Canal was designed to discharge the canal flow at high velocity into the Lahontan Reservoir; but, when the water was turned in, it was found that with small discharges a vertical curve at the bottom of the chute was sufficient obstruction to cause the water to jump to the upper low-velocity stage, which was so high that it began to overtop the concrete sides and had to be retained by sand bags before the discharge increased sufficiently to maintain the lower stage throughout the length of the chute.

6.—Destructive High Velocity Below Spillway Dams.

The jump shown in Fig. 11 illustrates what happens down stream from a spillway dam, except that in the case of a high spillway dam the elevation of the gradient up stream from the dam is fixed at the pond level and down stream from the dam it is fixed by the natural stream. The fixed difference between the two, or the net fall at the dam, is so much greater than the drop shown in Fig. 11 that the water cannot easily be made to jump to the upper stage until enough of the superfluous energy has been destroyed in friction, etc., so that the remainder of the drop can be absorbed by the eddies and disturbance accompanying the jump. Take, for example, the case of the very high dam shown in Fig. 12. As in previous figures, the dotted line represents the stage alternative to the water surface. The friction under the excessive velocity causes the hydraulic gradient to slope down steeply, and the two alternative stages to approach each other until they are near enough for the jump to occur between them, with its accompanying eddies destroying the remainder of the energy, as already explained. The horizontal scale is contracted, due to the limits of the size of the drawing.

In Fig. 12 the profiles of the hydraulic gradient and alternative stages are more or less arbitrarily drawn, but they illustrate the great vertical distance between the two theoretic alternative stages, and the consequent tendency of the destructive high-velocity flow to continue

* *Engineering Record*, April 10th, 1915.

some little distance down stream from the dam. This is further illustrated in Fig. 1, showing the Granite Reef Dam of the Salt River project of the U. S. Reclamation Service.

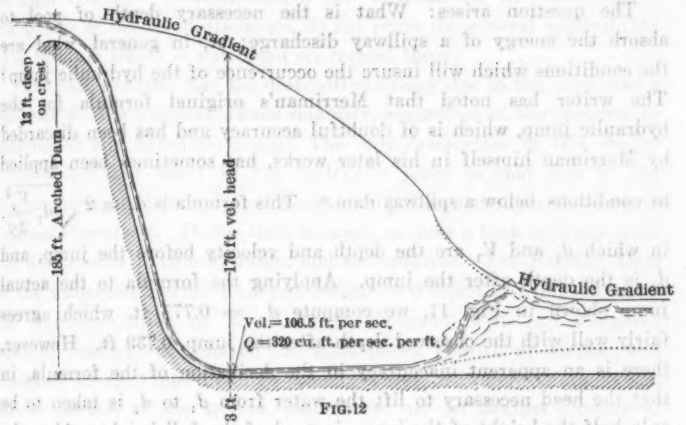

FIG. 12

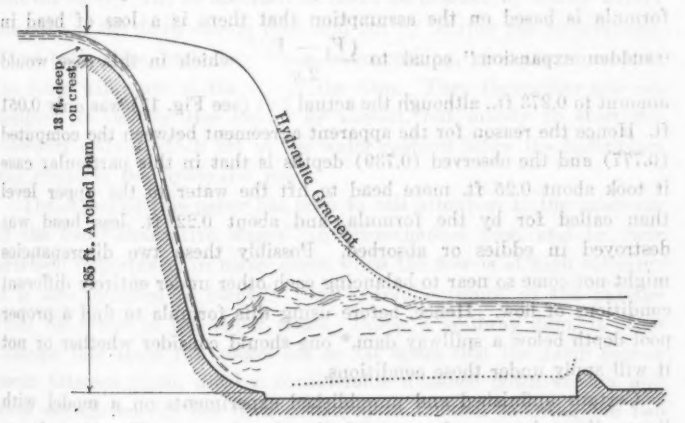

FIG. 13

Experience with actual spillways, as well as experiments on models, have shown that this tendency is counteracted, and the jump apparently brought back to the toe of the dam, if the pool into which the water plunges is deep enough. For example, as illustrated in Fig. 13, the

water-cushion is so deep, and the destruction of energy when the water strikes it is so great, that the total head is absorbed in this way, with no available energy left to maintain the high-velocity flow of Fig. 12.

The question arises: What is the necessary depth of pool to absorb the energy of a spillway discharge; or, in general, what are the conditions which will insure the occurrence of the hydraulic jump? The writer has noted that Merriman's original formula for the hydraulic jump, which is of doubtful accuracy and has been discarded by Merriman himself in his later works, has sometimes been applied to conditions below a spillway dam.* This formula is $d_2 = 2\sqrt{d_1 \frac{V_1^2}{2g}}$, in which d_1 and V_1 are the depth and velocity before the jump, and d_2 is the depth after the jump. Applying the formula to the actual jump shown in Fig. 11, we compute $d_2 = 0.777$ ft. which agrees fairly well with the observed depth after the jump, 0.739 ft. However, there is an apparent inaccuracy in the derivation of the formula, in that the head necessary to lift the water from d_1 to d_2 is taken to be only half the height of the jump, instead of the full height. Also, the formula is based on the assumption that there is a loss of head in "sudden expansion" equal to $\frac{(V_1 - V_2)^2}{2g}$, which in this case would amount to 0.273 ft., although the actual loss (see Fig. 11) was only 0.051 ft. Hence the reason for the apparent agreement between the computed (0.777) and the observed (0.739) depths is that in this particular case it took about 0.25 ft. more head to lift the water to the upper level than called for by the formula, and about 0.22 ft. less head was destroyed in eddies or absorbed. Possibly these two discrepancies might not come so near to balancing each other under entirely different conditions of flow. Hence, before using this formula to find a proper pool depth below a spillway dam,* one should consider whether or not it will apply under those conditions.

Certain unfinished and unpublished experiments on a model with linear dimensions one-forty-eighth the size shown in Fig. 13, indicate that, for these particular conditions also, at least in the model, the required amount of energy is destroyed and Merriman's original

* This use of the formula is not mentioned by Merriman, but has been made by other engineers. The latest edition of Merriman's "Hydraulics" treats the problem of the hydraulic jump differently.

formula gives approximately correct results, any pool depths greater than the computed 46 ft. causing the jump to occur at the toe of the dam and apparently preventing the water from shooting out straight at high velocity. Nevertheless, a few experiments not covering all conditions of head and discharge, do not prove the general applicability of a formula which is not based on correct theory.

The fact remains that the destructive energy due to the drop over a spillway dam is a definite, fixed quantity, regardless of the presence or absence of any hydraulic jump. The only destruction of this energy (conversion into heat) in the hydraulic jump is that due to the accompanying eddies and disturbances, and is measured by the drop in hydraulic gradient. If this drop is large, as over a high spillway dam, the disturbance is equally large, and unavoidable. The Bassano Dam of the Canadian Pacific Railroad Irrigation Project is equipped, after the recommendation of Mr. John R. Freeman, with two staggered rows of "baffle-piers", shaped like snow-plows, pointed up stream, and designed to split up the high-velocity sheet of water before it can strike the bed of the stream, and throw one jet against another so that the energy will be absorbed as much as possible by eddies within the body of the down-stream pool, and not by tearing the foundations. These baffle-piers, backed up by a water-cushion, give assurance that the jump will start at the toe of the dam. They themselves are not designed to destroy the energy by impact, but merely to start the necessary eddies, which act in the water-cushion below the baffle-piers and complete the hydraulic jump.

The object of this paper has been to call attention to the existence of the two "alternative stages" in open-channel flow, and to their practical importance, in many cases, when the flow is at high velocity; it is also intended to identify the "hydraulic jump" as the passage from the lower to the upper stage. Below a spillway dam, it often happens that these two stages are so far apart that the jump cannot occur between them, until a considerable distance down stream and after enough energy has been destroyed in friction to bring the two stages near together, as explained in the paper.

DISCUSSION

Mr. Groat. B. F. GROAT,* M. AM. SOC. C. E. (by letter).—The author has pointed out a principle which has commanded little or no attention. He has made clear the relations that control the limits of level within which the water in any channel must flow. Consequently, these relations control the upper limit of the possible rise of the hydraulic jump, although the effects of the channel and spillway conditions and, in particular, as Mr. Kennison indicates, the losses due to expanding cross-section, are still to be determined.

It appears that in any channel of usual shape there are two levels at which the water may flow with the same content of energy. Thus, so far as energy content is concerned, the water surface may change from one to the other of these levels without energy from any source other than that of the stream itself.

It also appears in the discussion, and this is clearly shown by Fig. 14, that the energy of the stream is always less for levels intermediate to the complementary levels, previously mentioned, than it is at either of them, and that it is greater outside of, than it is within, these limits. Therefore, the water cannot flow above the higher, or below the lower, of the complementary levels.

The great question is: What must happen at points between the two levels, at any of which there is a surplus of energy in the water? This surplus must appear in some form or another, the most likely being the energy which is absorbed by eddies. In other words, when the water surface is at either complementary level, does it not tend to move toward that intermediate level where the energy is a minimum? In the case of rectangular cross-sections, this level is at two-thirds the total energy head of the water; parabolic sections require three-fourths of the total energy head. At the foot of a dam the water may tend to rise to this level, but the rapid absorption of energy prevents it, as well as the fact that the shape of the channel below would not support such a flow in equilibrium, or there is no control section to support such a flow.

When the water surface is intermediate to the two complementary levels, it is certain that the formulas herein used do not apply, that is, the flow is not of the character supposed. In particular, the velocity is not uniform in the section, and there may be negative velocities, all of which destroy the value of the formulas for anything like accurate indications.

The height of the standing wave, for example, must depend on the shape, size, and character of the channel below the dam and also on the character of flow over the dam, as, for example, when changes of

FIG. 14.

Curve *A*.-Solution of the cubic equation $x^3-x^2+a=0$ for all values of a which furnish three real roots. This value of a is determined by the equation $a=-\frac{Q^2}{2\,g\,H^3}$ where Q is the discharge over one foot width of a dam and H the total hydrostatic head on the dam. A positive root of the equation represents the ratio of the theoretical depth below the dam to the total hydrostatic head, that is $x=d \div H$. The following limitations are noteworthy:

$0 < a < 4/27 = 2/3^3$

$-1/2 < x_1 < 0$

$0 < x_2 < 2/3$

$2/3 < x_3 < 1$

x_1, x_2, x_3 being the three roots of the equation, only one of which is negative for any admissible value of a.

Curve *B*.-Solution of the biquadratic equation $x^4-x^3+a=0$ for all values of a which furnish two real positive roots. These values of a are determined by the equation, $a=-\frac{Q^2}{2\,g\,k^2A^3}$, where $A=Kd^{3/2}$, A=area of cross-section of parabolic contour, d=the maximum depth above the bottom, $k=a$ constant, and H, as above, is the total hydrostatic head on the dam. A positive root of the equation is the ratio of the depth below the dam to the total hydrostatic head on the dam, or $x=d \div H$ as above.

The limitations are:

$0 < a < 27/256 = 3/4^4$

$0 < x_2 < 3/4$

$3/4 < x_3 < 1$

x_2 and x_3 being the two positive roots involved.

Q is the total discharge in the case of Curve *B*.

Mr. Groat.

condition of gate-opening occur in the case of arch dams provided with sluice-gates at the crest.

As the writer had the privilege of examining Mr. Kennison's treatment in connection with an important investigation, it may not be amiss to append some further study of the subject.

Fig. 14 solves problems relative to the two complementary levels for all channels having rectangular or parabolic cross-sections.

Using the author's notation, let:

$$a = \frac{Q^2}{2\,g\,H^3}, \text{ for rectangular sections;}$$

$$\text{and } a = \frac{Q^2}{2\,g\,K^2\,H^4}, \text{ for parabolic sections;}$$

where, in the latter case,

$$\text{the section area, } A = K\,x^{\frac{3}{2}}.$$

Let it be required, for example, to solve, by Fig. 14, the problem proposed by Mr. Kennison on page 344.

We have: $H = 10$ ft., $Q = 50$ cu. ft. per sec., and, therefore, $a = 50^2 \div 2\,g \times 10^3 = 0.0388$ for a rectangular section.

With this value of a, the corresponding values of the three ordinates to Curve A on Fig. 14, are 0.958, 0.224, and — 0.181.

As the curve relates to unit head, the three ordinates must be multiplied by H (10 ft. in this case), to secure the values of the corresponding depths. Therefore, the three possible depths for a total energy head of 10 ft. are 9.58 ft., 2.24 ft., and — 1.81 ft., of which the two positive values are the only ones sought. It will be seen that the results agree with the values deduced by Mr. Kennison by the solution of a cubic equation.

Curve B is used in exactly the same manner when the cross-section of the stream may be represented as the area of a parabola with its axis vertical and the vertex at the lowest point of the bed of the stream.

A better understanding of the subject and of the use of the curves will be gained by the following study of energy relations.

Rectangular Sections.—Let x be the depth in the channel, supposed to be rectangular, so that we need consider only 1 ft. of the width. The velocity is also supposed to be uniform, in order to simplify the discussion. Let v be the velocity and h the energy head. Then, the energy head at any point is given by

$$h = x + \frac{v^2}{2g} \quad \ldots\ldots(1)$$

If q is the discharge, we then have:

$$q = v\,x \quad \ldots\ldots(2)$$

or,

$$v = \frac{q}{x}$$

whence, $$x + \frac{q^2}{2\,g\,x^2} = h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

or, $$x^3 - h\,x^2 + \frac{q^2}{2\,g} = 0.$$

If, in Equation (3), we put

$$a = q^2 \div 2\,g\,h^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

and $$r = x \div h$$

there results,

$$r^3 - r^2 + a = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which a is a variable depending on the value of x, that is, on r. In other words, the energy head depends on the depth of the water in the section and varies in a sense contrary to that of the variation of a. Thus, when a is a maximum, the energy head is a minimum, and *vice versa*, if we suppose the discharge constant. If h is supposed to be constant, then the discharge is a maximum simultaneously with a.

If the discharge is supposed to be constant, then it is clear that there are two levels, as Mr. Kennison has pointed out, either of which can be maintained with the same energy head, h, as it can be shown that two of the roots of the cubic equations, (3), or (5), are positive, and the third is negative.

Let it be required to determine the relation between the two positive roots of Equation (5) so that, if one of the two possible levels of the water is known, the other can be found.

In order to do this, let n be the numerical value of the negative root of Equation (5). Then, by the theory of equations:

$$\frac{r^3 - r^2 + a}{r + n} \text{ is an exact quotient} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

that is,

$$r^2 - (n + 1)\,r + n\,(n + 1) = 0 \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

from which,

$$r = \frac{1 + n \pm \sqrt{(1 + n)\ \ (1 - 3\,n)}}{2} \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

This last equation determines the two positive roots in terms of the numerical value of the negative root. Table 1 has been computed by it, for the complete range of applicable values of r.

It will be seen from Equation (8) that n is limited to positive values which do not exceed $\frac{1}{3}$. At the limit 0, $r = 0$, or, $r = 1$, while the value, $\frac{1}{3}$, gives two equal values of r, that is, $\frac{2}{3}$ is a double root. This double root corresponds to a maximum value of a, and, consequently, to a minimum value of the energy head or to a maximum value of the discharge for a given energy head.

By Table 1, the graph of Equation (8) has been plotted as Curve *A*, on Fig. 14, which exhibits very clearly all the properties which have

Mr. Groat.

TABLE 1.—VALUES OF r, FOR THE EQUATION,

$$r^3 - r^2 + a = 0.$$

$\frac{4}{27}$	$\frac{1}{3}$	0	$\frac{2}{3}$	$\frac{2}{3}$

been discussed and, in addition, that there is a double root, 0, which corresponds to a minimum value of a. This is also clearly shown by Equation (8).

An illustration of the use of the curve has already been given.

It is now desirable to express one of the positive roots of Equation (5) in terms of the other, so that, if the depth of water in a channel is known, the complementary depth for the equal energy head can be determined by a simple formula.

In order to deduce this formula, observe that, if d_1 and d_2 are the two complementary depths, one of which, say, d_2, is known, then the two corresponding complementary roots of Equation (7) are $r_1 = d_1 \div h$, and $r_2 = d_2 \div h$, and they furnish, therefore, the following two equations:

$$\left.\begin{aligned} r_1^2 - (n+1)\, r_1 + n\,(n+1) &= 0 \\ r_2^2 - (n+1)\, r_2 + n\,(n+1) &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots (9)$$

As these equations must consist with each other, the relation between r_1 and r_2 may be deduced by eliminating n from them. This elimination may be effected most simply by taking the difference between the equations, thus:

$$r_1^2 - r_2^2 + (r_2 - r_1)\,(n+1) = 0 \ldots\ldots\ldots\ldots (10)$$

from which,

$$n + 1 = r_1 + r_2 \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

This relation might easily have been inferred from Equation (5), as the coefficient of r^2 is -1, that is,

$$n - r_1 - r_2 = -1 \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

is the negative sum of the roots.

Substituting the values of n and $n + 1$ in either form of Equation (9), it is easy to show that

Mr. Groat.

$$r_1^2 + (r_2 - 1)\, r_1 + (r_2^2 - r_2) = 0 \quad \ldots\ldots\ldots\ldots (13)$$

which gives r_1 in terms of r_2 thus:

$$r_1 = \frac{(1 - r_2) + \sqrt{(1 - r_2)\ (1 + 3\, r_2)}}{2} \quad \ldots\ldots\ldots\ldots (14)$$

the negative radical being omitted from the numerator as both d_1 and d_2, and, therefore, both the roots must be positive.

It will be more convenient, however, to have d_1 and d_2 expressed directly as functions of each other. This may be accomplished by substituting for r_1 and r_2 in Equation (14), thus

$$\frac{d_1}{h} = \frac{1 - \frac{d_2}{h} + \sqrt{\left(1 - \frac{d_2}{h}\right)\left(1 + \frac{3\, d_2}{h}\right)}}{2} \quad \ldots\ldots\ldots (15)$$

from which,

$$d_1 = \frac{h - d_2 + \sqrt{(h - d_2)\ (h + 3\, d_2)}}{2} \quad \ldots\ldots\ldots\ldots (16)$$

and, by observing that

$$h = d_2 + \frac{v_2^2}{2\, g},$$

we may easily obtain,

$$d_1 = \frac{\frac{v_2^2}{2\, g} + \sqrt{\frac{v_2^2}{2\, g}\left(\frac{v_2^2}{2\, g} + 4\, d_2\right)}}{2} \quad \ldots\ldots\ldots\ldots (17)$$

or,

$$d_1 = \frac{v_2^2}{2\, g}\left(\frac{1}{2} + \sqrt{\frac{1}{4} + R}\right)$$

where,

$$R = \frac{d_2}{\frac{v_2^2}{2\, g}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

R thus being the ratio of potential to velocity head.

Thus, d_2 being 2.24, and $v_2^2 \div 2\, g$ being 7.76, we should have $R = 2.24 \div 7.76 = 0.289$, from which,

$$d_1 = 7.76\ (0.5 + \sqrt{0.539}) = 9.58 \quad \ldots\ldots\ldots\ldots (19)$$

which agrees with Mr. Kennison's value on page 344. If we take $d_2 = 9.58$ and $v_2^2 \div 2\, g = 0.42$, in Equation (17), it will be found that $d_1 = 2.24$ and $v_1^2 \div 2\, g = 7.76$, a necessary result due to the reciprocal relation between d_1 and d_2. (See Equations (20).)

Mr. Groat.

Equation (17) may be deduced directly by solving

$$d_1 + \frac{v_1^2}{2g} = d_2 + \frac{v_2^2}{2g} \quad \ldots\ldots (20)$$

and,

$$d_1 v_1 = d_2 v_2$$

for d_1 in terms of d_2 after cancelling the factor, $d_1 - d_2$.

Now, it is easy to see that $0 < r_1 < \frac{2}{3}$ and $\frac{2}{3} < r_2 < 1$, and that either the equation, $r^3 - r^2 + a = 0$, or Fig. 14, showing the trace of the relation between a and r, shows that a is greater for all values of r between r_1 and r_2 than it is for r_1 or r_2; that is, h, the energy head of the flowing water, for all depths between d_1 and d_2, is less than it is at either of these limits, and the energy is greater at depths below d_1 or above d_2. Hence, the flow of the water is limited to some depth, x, where $d_1 < x < d_2$. That is, the water may flow at any level between d_1 and d_2, but not outside these limits. This, of course, supposes a rectangular channel and that a sufficient amount of energy is absorbed where the level is at neither limit.

Parabolic Cross-Sections.—The foregoing method of analysis may be extended to shapes of section other than rectangular with corresponding modifications. Suppose, for example, that the section area is connected to the depth by

$$A = k x^{\frac{3}{2}} \quad \ldots\ldots (21)$$

A being the area, x the depth, as before, and k a constant.

Then,

$$h = x + \frac{v^2}{2g} \quad \ldots\ldots (22)$$

$$q = A v. \quad \ldots\ldots (23)$$

and,

$$v = \frac{q}{A} = \frac{q}{k x^{\frac{3}{2}}} \quad \ldots\ldots (24)$$

Therefore,

$$h = x + \frac{q^2}{2g k^2 x^3} \quad \ldots\ldots (25)$$

$$x^4 - h x^3 + \frac{q^2}{2g k^2} = 0 \quad \ldots\ldots (26)$$

from which,

$$r^4 - r^3 + \frac{q^2}{2g k^2 h^4} = 0$$

or,

$$r^4 - r^3 + a = 0 \quad \ldots\ldots (27)$$

where,

$$a = \frac{q^2}{2g k^2 h^4} \quad \ldots\ldots (28)$$

and,

$$r = x \div h.$$

Mr. Groat.

It is then easy to show, by reasoning exactly as in the case of a rectangular channel, that a is a maximum and H a minimum when $r = \frac{3}{4}$, that is, when the depth is three-fourths of the total energy head. The graph of the equation for the applicable values of the roots may be constructed from Table 2.

TABLE 2.—VALUES OF r FOR THE EQUATION,

$$r^4 - r^3 + a = 0.$$

r	r^3	r^4	a	Remarks.

0.7	0.3430	0.2401	0.1029	
¾	0.4219	0.3164	0.1055*	$(\frac{3}{4})^3(1-\frac{3}{4}) =$ maximum value of $a = \frac{3^3}{4^4}$.
0.8	0.5120	0.4096	0.1024	
0.9	0.7290	0.6561	0.0729	
1.0	1	1	0	

The curve is marked B on Fig. 14. Only two positive roots are applicable, there being a pair of imaginary roots for the admissible range in value of a, the maximum of which is $3^3 \div 4^4 = 0.1055$, when $r = \frac{3}{4}$.

Let it be required, as in the former case, to deduce the relation between the two positive roots, and thus a formula for determining the second possible water level when the first is known, supposing that no losses of energy occur in the change.

This may be accomplished by a procedure analogous to that adopted in the case of rectangular cross-sections, but the following will probably be found more expeditious:

Let d_1 and d_2 be the two possible levels. We then have,

$$d_1 + \frac{v_1^2}{2g} = d_2 + \frac{v_2^2}{2g} \quad \ldots\ldots(29)$$

but,
$$v^2 = q^2 \div A^2 = q^2 \div K^2 x^3 \quad \ldots\ldots(30)$$

therefore,
$$d_1 - d_2 = \frac{q^2}{2gK^2}\left(\frac{1}{d_2^3} - \frac{1}{d_1^3}\right)$$
$$= \frac{q^2}{2gK^2}\,\frac{d_1^3 - d_2^3}{d_1^3 d_2^3} \quad \ldots\ldots(31)$$

Mr. Groat.

from which we easily find

$$1 = \frac{q^2}{2\,g\,K^2\,h^4}\,\frac{d_1}{r_1^4}\,\frac{d_1^2 + d_2\,d_1 + d_2^2}{d_2^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots (32)$$

Thus, by Equation (28),

$$1 = \frac{a}{r_1^4}\,(R^3 + R^2 + R) \quad \ldots\ldots\ldots\ldots\ldots\ldots (33)$$

or,

$$R^3 + R^2 + R - b = 0,$$

where R is the ratio of the two applicable roots, and,

$$b = \frac{r_1^4}{a} = \frac{d_1}{\frac{v_1^2}{2\,g}} = \frac{r_1}{1 - r_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (34)$$

It may be shown that two of the roots are imaginary for all applicable values of b, that is, of a and r_1, so that there will be only one solution, which is given by,

$$A = \frac{7}{54} + \frac{b}{2}$$

$$B = \sqrt{A^2 + \left(\frac{2}{9}\right)^3}$$

$$R = (A + B)^{\frac{1}{3}} + (A - B)^{\frac{1}{3}} - \frac{1}{3} \quad \ldots\ldots\ldots\ldots\ldots\ldots (35)$$

For example, if $r_1 = 0.45$, then $b = 45 \div 55 = 9 \div 11 = 0.8181$ and $a = 0.050119$, from which,

$$A = \frac{7}{54} + \frac{b}{2} = 0.538720$$

$$B = \sqrt{A^2 + \left(\frac{2}{9}\right)^3} = 0.548811$$

$$A + B = 1.087531$$

$$A - B = -\,0.010091$$

and

$$R = 1.087531^{\frac{1}{3}} - 0.010091^{\frac{1}{3}} - \frac{1}{3}$$

$$= 1.028365 - 0.216094 - \frac{1}{3}$$

$$= 0.47894.$$

Therefore, we must have,

$$r_2 = \frac{r_1}{R} = \frac{0.45}{0.47894} = 0.93957,$$

the correctness of which may be verified by reference to Fig. 14, for $a = 0.0501$. It will be seen that the two values of r, for this value of a, agree with the values just computed.

Mr. Groat.

It is now easy to see how any shape of cross-section can be treated in a manner similar to the foregoing, whether the section is, or is not, expressible in algebraic form. It is also clear, from the foregoing treatment, that the complementary levels vary relatively for different shapes of section, and that the elevation of the water surface in control sections also depends on the shape as well as on the magnitude of the sections, being two-thirds of the total energy head for rectangular sections and three-quarters of the energy head for parabolic sections. The jump, likewise, is governed by the shape of the channel.

An interesting question arises in the case of cross-sections other than rectangular. If individual widths are treated separately, it will be found that the corresponding complementary levels vary according to location across the stream. That is, theoretically, the water surface should present a curved transverse profile. May this not be one of the prime causes of much of the disturbance which occurs in streams of irregular cross-section?

The writer is of the opinion that we wander too far from the domain of theoretical hydrodynamics when we apply equilibrium equations to finite masses and volumes of water. This can be done with exactness only when we are considering rigid bodies. The difficulty has always been that of integrating the differential equations throughout the volumes and over the bounding surfaces of the masses of water involved. However, much progress has been made and still more remains for the future. In time, we shall understand the nature of the losses which occur by reason of expanding sections in draft-tubes and in the hydraulic jump. Mathematics and experimental physics must join hands in the work. Fortunately, the density is practically constant, which simplifies matters considerably, but our knowledge of the effects of viscosity is very limited.

Varied examples of the hydraulic jump may be seen at most sea beaches where the slope is not too steep. A favorable condition occurs when the slope is moderate for a considerable distance up the beach followed by a steeper slope above. The steeper slope aids in accelerating the water receding down the beach. When the receding water attains the right velocity with respect to an incoming wave, the jump occurs. These jumps seldom exceed 1 ft. in height, but present an interesting variety of phenomena.

Mr. Muckleston.

H. B. MUCKLESTON,* M. AM. SOC. C. E. (by letter).—This interesting paper should be very valuable to those who have to deal with the phenomena discussed. Two instances are cited where the question proved important for widely different reasons, and many others will readily occur to the reader.

It will be understood that the formulas presented are like all other hydraulic formulas founded on incomplete theory, or probably—put in

* Calgary, Alberta, Canada.

Mr. Muckleston.

a better way—on theory founded on incomplete or erroneous assumptions, and that in practice they will have to be modified by a coefficient.

The author points out one case, in the application to weir discharge, where the theoretical formula must be modified to agree with the results of experiment.

On page 344 the author makes the convenient but inaccurate assumption that the velocity head of a flowing stream is equal to $\frac{V^2}{2g}$, where V is equal to the discharge divided by the cross-sectional area. This is never quite true, and in extreme cases may be very far from the truth. Assume, for example, a stream divided into two parts, and that the mean velocity is 14 ft. per sec. in the upper part and 2 ft. per sec. in the lower. On the author's assumption, the velocity head for the whole would be 1.0 ft., nearly. Taking the two values separately, and using the mean of the values thus found, it would be about 1.56 ft.

The case is extreme, and probably impossible, but it serves to show that the assumption is not correct.

Referring now to the case of the Bassano Dam, cited by the author and illustrated by Fig. 2: This dam is about 38 ft. high above the down-stream apron, and may discharge about 13 ft. deep over the crest. The concrete apron below the ogee is about 50 ft. long, and it was feared that at certain stages the jump or standing wave might be pushed down stream to such a distance that it would occur on the unprotected river bed, which in this case is gravel overlying clay. In order to insure that this should not occur, on the recommendation of Mr. John R. Freeman, two rows of baffle piers were built on the ogee, as described by the author. The dam has now been through two seasons and one very large flood, and it may be interesting to give the results of close observation of the behavior of these baffles.

Owing to the presence of two large under-sluices near the center of the dam at apron level, a length of 60 ft. was not equipped with them, and another length next to the east abutment was left unprovided on account of a turbine outlet. There was thus an opportunity to observe closely, especially at moderate stages, the results of building these baffles. It should be noticed that the level of the stream below the dam rises very much faster than does the pond above, and that, in consequence, the depth of cushion increases very much faster than the discharge. For instance, with about 4 ft. on the crest, the depth on the apron is about the same; for 10 ft. on the crest, the depth on the apron was about 18 ft.

It was noticed that at very low stages, say, less than 3 ft., the stream striking the baffles was so thin that practically all the energy was absorbed by impact. As the stage increased, the effect of the baffles was seen in a series of jets which did not impinge on one an-

FIG. 15.—BASSANO DAM: OVERFLOW WITH 5.5 FT. ON THE CREST.

FIG. 16.—BASSANO DAM: OVERFLOW WITH 9.5 FT. ON THE CREST.

CAMBRIDGE
INDIA PAPER

Mr. Muckleston.

other, but, on the contrary, were thrown out on the apron, especially the jets from the upper row. This effect increased in volume up to a stage of about 6.5 ft., when the depth on the carpet began to mask the baffles, and the violence of the jets began to decrease, until at a stage of about 8.5 ft. the action of the baffles was completely obscured by the water-cushion.

Considering that part where no baffles were provided, it was observed that for stages up to about 3 ft. the jump occurred on the ogee. (The stage varies because the depth of cushion for any given stage varies somewhat on account of the condition of the stream bed below.) From this up to about 7 ft. the jump is pushed down stream for a short distance, estimated at about 20 ft., after which it begins to return. Figs. 15 and 16, reproduced from photographs taken from nearly the same point, illustrate the action at two different stages. Fig. 15 shows the dam at about 5.5 ft. on the crest. The unequipped length is very evident, as is also the action of the baffles in throwing out the almost horizontal jets. Fig. 16, showing the dam with 9.5 ft. on the crest, is specially interesting, when compared with Fig. 15. The section of the dam not equipped is not at all evident, and cannot be located except by counting the bridge piers. Looking down from the bridge, there did not appear to be any difference in the action of the two parts.

The author's conclusions are interesting and valuable, but there is a further conclusion which he did not draw. The writer is of the opinion that the ogee is the wrong method of treating a spillway dam, and that any device which may be added to minimize its bad effects is only a palliative and not a cure. A straight overfall into a deep water-cushion is Nature's method, and, if adopted in the work of Man, no evil effects from jump, back roll, standing wave, or whatever it may be called, need be feared. As far as the writer knows, this has never been investigated, except as regards the effects on the floor of the cushion. Many years ago, Col. Dyas experimented in India by sending thin glass bottles over falls, and observed that they were not broken when the depth of the cushion exceeded $h^{\frac{1}{2}} d^{\frac{1}{3}}$, where h is the height of the fall and d is the depth on the crest. For design, this was modified to one-half or one-third of the depth thus found, depending on the material of the floor.

Mr. Stearns.

FREDERIC P. STEARNS,* PAST-PRESIDENT, AM. SOC. C. E. (by letter).—This paper is a very valuable contribution on a subject which has rarely been discussed, but is of high practical importance. The treatment of the subject by the author from a theoretical and mathematical standpoint is so complete that the writer can add nothing of value in these respects.

* Boston, Mass.

Mr. Stearns.

The author makes this statement:

"A knowledge of the hydraulic principles involved [in the hydraulic jump] should enable destructive high velocities and turbulence to be avoided, or intelligently provided for, in the design of flumes, dam foundations, etc."

Elsewhere in the paper, also, he calls attention to the practical dangers of permitting water to flow with high velocity at the lower "alternative stage". It seems desirable that the dangers involved in such high velocities and the methods by which they may be prevented should be still further emphasized.

In the writer's experience, damage occurred to a wooden flume, referred to in the paper, because the water flowed at the lower "alternative stage" for a long distance before the hydraulic jump occurred. The flume, 40 ft. wide, 16 ft. high at its upper end, and 13 ft. at the lower end, was built to carry the water of a stream past a masonry dam during the construction of its lower portion. It was built of planed lumber, with no obstructions on the inside. Its total length was about 700 ft. At a point 380 ft. from its upper end there was an angle in the flume, the deflection from a straight line being 8.5 degrees. The approach was flared, to prevent losses of head due to contraction at the entrance.

The upper end of the flume passed through an earth coffer-dam, and, on the center line of the latter, 30 ft. below the entrance to the flume, provision was made for removable stop-logs, which were kept in place except during floods to maintain a water supply through an aqueduct. The plans provided for a coffer-dam across the valley at the lower end of the flume, but at the time of the floods referred to subsequently this dam had not been built.

In designing the flume, the maximum quantity of water to be discharged during the greatest floods was assumed to be 9 000 cu. ft. per sec., and it was expected that with this discharge there would be a loss of head at the entrance of about 5 ft., and that the flume would run nearly full.

The writer recognized at that time that immediately below where the drop in the surface occurred, at the entrance to the flume, the water surface might be lower than at points farther down stream, but there was nothing in his experience or that he had gleaned from the experience of others to lead him to think that the low-water surface would persist for any long distance.

A flood substantially equal to that assumed in designing the flume occurred, and the flume operated substantially in accordance with the expectations at the time it was designed, as there was a moderate loss of head at the entrance and the flume ran nearly full.

Soon afterward, a second flood occurred, somewhat smaller than the first, but the water, instead of nearly filling the flume, ran with high

velocity with a depth of less than half the height of the flume, until it reached the slight angle 380 ft. from its upper end. The hydraulic jump then took place, not all at once, but rather gradually, in the next 275 ft. The water on the outside of the flume, corresponding as it did to the height of water at its lower end, was from 1 to 2 ft. higher than the water inside, where it was flowing at the low stage, thereby causing an upward pressure on the bottom sufficient to lift the flume off its foundation for a considerable part of its length, notwithstanding the fact that it was anchored in some places to the ledge and in other places was fastened to anchors buried 3 ft. below the surface of the ground which supported the sills. Mr. Stearns.

Just why the water flowed at such different depths in the flume in the two floods is not definitely known, but it is probable that it was due to the removal of all the stop-logs and other obstructions at the time of the first flood and to leaving a part of these logs in place during the second flood. The author illustrates the conditions toward the upper end of this flume in Fig. 10.

The damage done to the flume might have been avoided had some comparatively small obstructions been placed in its bottom toward the upper end, so as to cause the hydraulic jump to take place there. Very few flumes are built where the damage which occurred in this case would be likely to occur, and the incident has been fully described in order to illustrate a cause of danger which is frequently present below spillway dams.

Taking now the case of a high spillway dam, like that illustrated by Fig. 12, the water attains a high velocity as the result of the fall from the reservoir, and, owing to the easy curve at the bottom of the dam, is projected horizontally along an apron, with the velocity still high, and a correspondingly small depth, but at a greater or less distance below the dam the hydraulic jump occurs, and down stream from this jump the water is much higher than above it.

Assuming, in a case like that described and illustrated, that there is a level concrete apron without vents to relieve the pressure beneath it, over which the water moves with high velocity, and that the hydraulic jump takes place at the lower edge of the apron, it will then seem obvious that the water pressure beneath the apron will be that due to the comparatively high level of the water down stream from the hydraulic jump, although this may be somewhat increased by the pressure transmitted from the reservoir itself through the strata beneath the dam. In other words, the pressure tending to lift the concrete apron will not be less than that represented by the difference of level between the surface of the swiftly moving water up stream from the jump and the slower moving water down stream from it. If the excess of pressure beneath the apron is greater than the weight of the apron, it will lift.

Mr. Stearns.

The author's Fig. 12, based on a spillway dam 185 ft. high, is, so he states, "more or less arbitrarily drawn", but it is sufficiently near what may occur in practice to be used for the purpose of illustration. By scaling from the illustration, the jump from the low stage to the high one is 34 ft., and if the level portion below the dam was a concrete apron without vents, a thickness of fully 23 ft. would be required to balance this net head, assuming the concrete when immersed in water to weigh 90 lb. per cu. ft.

It is frequently the case that there is trouble below spillway dams as the result of heavy floods, and an important factor in causing such trouble is a failure to stop the high velocity close to the foot of the dam.

High velocity below a dam may cause trouble in two ways:

(*a*)—In the manner already described, owing to the small pressure of the swiftly moving water on the top of a nearly level apron, or on the surface of a ledge, in comparison with the pressure under the apron, or in the seams of the ledge when these communicate with the slowly moving water at a higher level below the jump;

(*b*)—By reason of the swiftly moving water impinging upon a crack or seam facing up stream, thereby causing in the crack or seam the increased pressure due to the velocity of the water, much in the same way that increased pressure or head is produced in a Pitot tube used in a swiftly moving stream when the orifice faces the current.

From one or the other or both of these causes, aprons may be lifted, great masses of rock lying in horizontal strata may be displaced, and holes may be dug in the rock below important spillway dams to an extent that seems nearly incredible to those who have not witnessed the results or studied the forces acting to produce such movements.

The author makes this statement, on page 353:

"The fact remains that the destructive energy due to the drop over a spillway dam is a definite, fixed quantity, regardless of the presence or absence of any hydraulic jump."

The writer agrees with this statement, if the word "destructive" is omitted.

There is a definite amount of energy due to the fall of the water, but it may or may not be destructive. Water may fall through a turbine, converting the energy due to the drop into other forms of energy, and yet be in no wise destructive. Similarly, the energy due to the drop over a spillway dam may be converted into heat close to the foot of the dam, without being destructive, if the material upon which the water drops can be depended on to endure the shock and wear caused by the swiftly moving water and by all other substances which are carried by it over the dam.

The common practice of curving the bottom of a concrete dam, so as to throw the sheet of water out in a nearly horizontal direction with

Mr. Stearns.

little loss of velocity, is one which seems to have had its origin either in the idea that this changing of the direction of the water would prevent erosion of the material below the dam, or that the material used in constructing the dam could not be depended on to stand the shock of the falling water and other substances. The use of this bottom curve has signally failed to prevent the erosion of rock and other material below a dam, and materials are now available for constructing dams, which under most circumstances can be depended on to endure the shock and wear resulting from the drop of the water in great quantities over a very high dam.

The writer believes that the policy in respect to the lower portion of spillway dams should be modified, and that the high velocity should be destroyed at the point where the water reaches the bottom of the dam, and not be merely changed in direction.

The high-grade concrete which it is feasible to make at the present day, if used in sufficient thicknesses and amply reinforced with steel, can be depended on in nearly all cases to endure the shock and wear caused by water and all other substances which fall over a dam, and, if necessary, points subject to excessive shock and wear can be faced with cast iron. The shock can be greatly lessened, where it is feasible to provide an adequate water-cushion.

The method to be used in different cases will naturally vary. On page 353 the author has referred to one method:

"The Bassano Dam of the Canadian Pacific Railroad Irrigation Project is equipped, after the recommendation of Mr. John R. Freeman, with two staggered rows of 'baffle-piers', shaped like snow-plows, pointed up stream, and designed to split up the high-velocity sheet of water before it can strike the bed of the stream, and throw one jet against another so that the energy will be absorbed as much as possible by eddies within the body of the down-stream pool, and not by tearing the foundations. These baffle-piers, backed up by a water-cushion, give assurance that the jump will start at the toe of the dam."

Fig. 2 is a view of this dam in action.

The writer, as already indicated, believes that, as a rule, a more complete destruction of the high velocity at the foot of the dam should be attempted. One method of doing this is indicated by Fig. 17, which represents (with slight modification) the arrangements provided at a spillway dam designed in part by the writer.

It was necessary in this case, and it is frequently necessary in order to obtain a suitable foundation for a dam, to excavate to a considerable depth below the river bed, and if the down-stream face of the dam is continued to below the bed without a curve, and the excavation on the down-stream side is filled with concrete to a level below the bed, a large thickness of concrete upon which a sheet of water may strike is easily provided; also a water-cushion.

Mr. Stearns.

The sketch, Fig. 17, illustrates this method of construction. The concrete on the down-stream side is built to a level about 5 ft. below the river bed, and 15 ft. from the down-stream face a wall is built to the level of the river bed. By such an arrangement, there is a pool having a depth of 5 ft. in addition to the depth to which the water rises above the river bed with different river discharges. If, in the case of a big flood, the water in the river rises 10 ft., the sheet will fall into a pool 15 ft. deep.

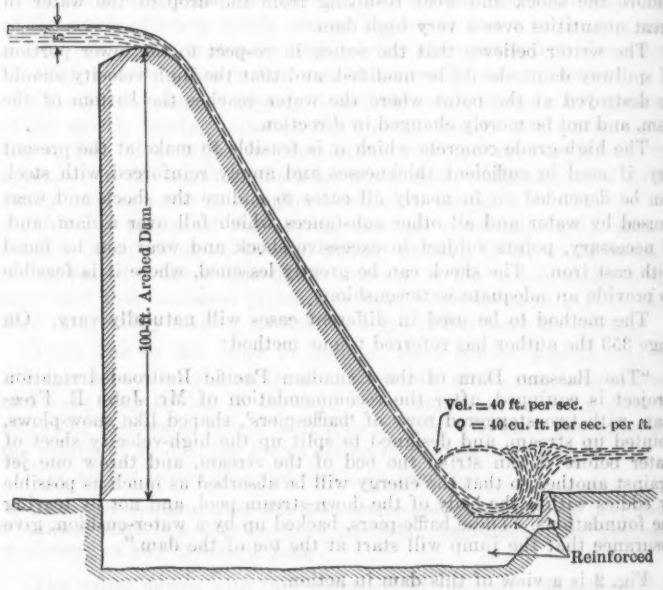

FIG. 17.

In order to visualize the conditions existing at such a dam during a maximum flood, let it be assumed that the maximum depth on the crest will be substantially 5 ft. and the quantity of water per linear foot 40 cu. ft. per sec. The velocity of the descending water, where it enters the pool at the foot of the dam, will be between 30 and 60 ft. per sec., making the depth of the sheet at this place between 16 and 8 in.

To use an intermediate figure between these limits, it may be assumed for the purpose of discussion that the sheet will be 1 ft. thick and have a velocity of 40 ft. per sec. Water with this velocity entering the pool at the face of the dam would obviously continue to flow down

the face to the bottom of the pool. It would entrain some of the water through which it passed, thereby decreasing the velocity and increasing the thickness of the moving mass. On reaching the bottom, the water would be deflected down stream, and would flow with still diminishing velocity, for the most part horizontally, until its motion was retarded by the wall 15 ft. from the dam; thence it would flow upward, most of the water turning down stream, but a part of it turning up stream to take the place of the water entrained. Mr. Stearns.

It seems quite clear that with the proportions thus given for the depth of the pool and the thickness of the flowing sheet, the energy due to the drop of 100 ft. would be thoroughly taken care of in the pool within 15 or 20 ft. of the bottom of the down-stream slope, without destructive action, and that at points farther down stream there would be no high velocity due to the fall of the water over the dam.

If there was any doubt as to the action thus described taking place in a pool at the base of a dam, the further precaution might be taken of building occasional projections from the face of the dam, irregularly spaced at different distances below the flood level in the river. Such projections should be strong enough to resist all shocks, and would deflect parts of the sheet of water, making it impossible for it to flow at the lower "alternative stage". The confused currents caused by such projections would quickly entrain large quantities of the water in a pool, thereby producing a fairly regular flow within a very short distance from the foot of the dam.

The design of the spillway at the Gatun Dam at the Panama Canal contains features to be commended, especially in cases where the quantity of water per linear foot of spillway is very large. In this case, the raising of large gates on the spillway crest, 18 ft. lower than the reservoir at its maximum level, causes great volumes of water per linear foot to flow over the dam. The drop from the crest to the concrete apron at the foot of the dam is 59 ft., and the thickness of the apron where the water falls upon it is about 12 ft. Projecting above the apron, close to the foot of the dam, there are two rows of baffles with vertical up-stream faces, those in the upper row being about 18 ft. wide and 8 ft. high. The baffles in the two rows are staggered, so that the water passing between those in the upper row impinges upon those of the lower row. When in action, much of the water is thrown high into the air, with a nearly complete destruction of its horizontal velocity, and cross-currents are also formed. The total result is that most of the energy of the water is taken care of at the baffles, and beyond them the water flows away with a comparatively low velocity. The baffles are faced on the up-stream side with heavy cast iron anchored to them, and these in turn are securely anchored by reinforcing rods to the mass of concrete beneath.

Mr. Stearns.

It seems unnecessary to multiply illustrations. There are many expedients by which the high velocity of the water falling over a dam can be checked very close to its foot, and the dangerous features of the high velocity and the hydraulic jump farther down stream can be avoided.

Mr. Andrews.

CARL B. ANDREWS,* ASSOC. M. AM. SOC. C. E. (by letter).—In the author's discussion of the depth of pool necessary to absorb the energy of a spillway discharge, he mentions Professor Merriman's original formula for height of jump. It would perhaps be only fair to Professor Merriman to quote the paragraph in connection with the development of this formula. It is as follows:

"To determine the height of the jump, let $d_2 - d_1$ be represented by j. It is then to be observed that the lost velocity-head is $(v_1^2 - v_2^2) \div 2\,g$, and that this is lost in two ways, first by the impact due to the expansion of section $\left[h' = \frac{(v_1 - v_2)^2}{2\,g}\right]$, and second by the uplifting of the whole quantity of water through the height, $\frac{1}{2}(d_2 - d_1)$, loss in friction between d_1 and d_2 being neglected.

Hence $$\frac{v_1^2 - v_2^2}{2\,g} = \frac{(v_1 - v_2)^2}{2\,g} + \frac{j}{2}.$$

Inserting in this the value of v_2, found from the relation $v_2\,(d_1 + j) = v_1\,d_1$, and solving for j, gives

$$j = -\,d_1 + 2\sqrt{d_1 \frac{v_1^2}{2\,g}}."$$

The subject of the height of jump has been treated by at least two other eminent engineers, Professor Hubert Engels, and Professor W. C. Unwin. Professor Engels, in his recently published "Handbuch des Wasserbaues," deduces the approximate height of the jump, as follows: The height of the jump may be obtained approximately with the aid of the law of kinetic energy, by equating the difference between the two velocity heads to the difference between the two water surfaces, or (in Fig. 18),

$$\frac{v_2^2}{2\,g} - \frac{v_1^2}{2\,g} = d_1 - d_2$$

or, since $$v_2 = v_1 \frac{d_1}{d_2},$$

and letting $$\frac{v_1}{2\,g} = k.$$

$$\frac{1}{2\,g}\left[v_1^2 \frac{d_1^2}{d_2^2} - v_1^2\right] = \frac{v_1^2}{2\,g}\left[\frac{d_1^2 - d_2^2}{d_2^2}\right] = d_1 - d_2$$

* Honolulu, Hawaii.

or $$\frac{v_1^2}{2g}\left[\frac{d_1 + d_2}{d_2^2}\right] = 1$$

or $$k\left[\frac{d_1 + d_2}{d_2^2}\right] = 1$$

whence, $$d_2^2 - k\,d_2 = k\,d_1$$

$$d_2 = \frac{k}{2} + \sqrt{k\,d_1 + \frac{k^2}{4}} = \frac{v_1^2}{4g} + \sqrt{\frac{v_1^2}{2g}d_1 + \left(\frac{v_1^2}{4g}\right)^2}$$

or $$j = -\,d_1 + \frac{v_1^2}{4g} + \sqrt{\frac{v_1^2}{2g}d_1 + \left(\frac{v_1^2}{4g}\right)^2}.$$

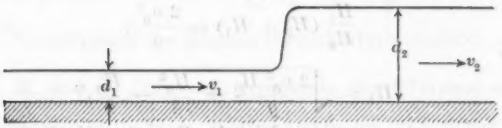

FIG. 18.

Professor Unwin's treatment of the problem appears in the *Encyclopedia Britannica*, under the head of "Hydraulics". He writes:

"Let the figure [Fig. 19] represent the longitudinal section of a stream and *ab*, *cd*, cross-sections normal to the bed, which for the short distance considered may be assumed horizontal. Suppose the mass of water *abcd* to come to $a'b'c'd'$ in a short time t; and let u_0, u_1, be the velocities at *ab* and *cd*, Ω_0 and Ω_1 the areas of the cross-sections. The force causing change of momentum in the mass *abcd* estimated horizontally is simply the difference of the pressures on *ab* and *cd*. Putting h_0, h_1, for the depths of the centers of gravity of *ab* and *cd* measured down from the free water surface, the force is $G\,(h_0\,\Omega_0 - h_1\,\Omega_1)$ pounds, [G = weight per cubic unit of liquid] and the impulse in t seconds is $G\,(h_0\,\Omega_0 - h_1\,\Omega_1)\,t$ second-pounds. The horizontal change of momentum is the difference of the momenta of $cdc'd'$ and $aba'b'$; that is,

$$\frac{G}{g}\,(\Omega_1\,u_1^2 - \Omega_0\,u_0^2)\,t.$$

Hence, equating impulse and change of momentum,

$$G\,(h_0\,\Omega_0 - h_1\,\Omega_1)\,t = \frac{G}{g}\,(\Omega_1\,u_1^2 - \Omega_0\,u_0^2)\,;$$

Hence $$h_0\,\Omega_0 - h_1\,\Omega_1 = \frac{1}{g}\,(\Omega_1\,u_1^2 - \Omega_0\,u_0^2).$$

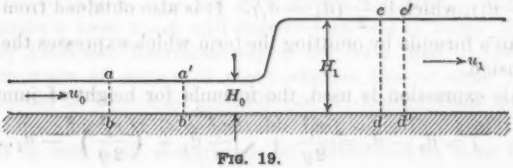

FIG. 19.

Mr. Andrews.

"For simplicity let the section be rectangular, of breadth B and depths H_0 and H_1 at the two cross-sections considered; then $h_0 = \frac{1}{2} H_0$, and $h_1 = \frac{1}{2} H_1$. Hence

$$H_0^2 - H_1^2 = \frac{2}{g} (H_1 u_1^2 - H_0 u_0^2).$$

$\frac{1}{2} (H_0^2 - H_1^2) = \frac{1}{g} [H_1 u_1^2 - H_0 u_0^2]$. But, since $\Omega_0 u_0 = \Omega_1 u_1$, we have $u_1^2 = u_0^2 \frac{H_0^2}{H_1^2}$ and $H_0^2 - H_1^2 = \frac{2 u_0^2}{g} \left[\frac{H_0^2}{H_1} - H_0\right]$

* * * * * * *

"Dividing by $H_0 - H_1$, the equation becomes

$$\frac{H_1}{H_0} (H_0 + H_1) = \frac{2 u_0^2}{g};$$

therefore

$$H_1 = \sqrt{\frac{2 u_0^2 H_0}{g} + \frac{H_0^2}{4}} - \frac{H_0}{2}."$$

The last equation, as printed in the *Encyclopedia Britannica*, contains a typographical error, the sign of the term, $\frac{H_0}{2}$, being there printed +.

A comparison of the Merriman, Engels, and Unwin formulas as given herein, will show that they are essentially different, and will not give the same result for any given set of data.

The writer hesitates to make what might be considered a criticism of the work of the eminent engineers whose names accompany the foregoing formulas, and what follows has been written in an endeavor to find the reason for the differences between them.

Referring to the development of the Engels formula, which he refers to as an approximate one, it seems as though the difference between the velocity heads should be equal to the difference between the heights of the centers of gravity of the water masses, in the two phases of flow, rather than equal to the difference of elevation of the two water surfaces. Thus, we should have $\frac{v_1^2 - v_2^2}{2g} = \frac{d_2 - d_1}{2} = \frac{j}{2}$.

This expression is also obtained by equating the loss of kinetic energy in any water mass, M, which is $\frac{1}{2} M (v_1^2 - v_2^2) = \frac{W}{2g} (v_1^2 - v_2^2)$, to the work done in raising the same mass through the height, $\frac{1}{2} (d_2 - d_1)$, which is $\frac{W}{2} (d_2 - d_1)$. It is also obtained from Professor Merriman's formula by omitting the term which expresses the head lost in expansion.

If this expression is used, the formula for height of jump will be:

$$j = d_2 - d_1 = \frac{v_1^2}{2g} + \sqrt{\frac{v_1^2}{g} d_1 + \left(\frac{v_1^2}{2g}\right)^2} - d_1 \ldots\ldots (A)$$

Mr. Andrews.

It appears as though Professor Unwin, in the development of his formula, has treated static pressure as if it were a dynamic force. He takes the difference of static pressures on planes, *ab* and *cd*, multiplies it by the time, *t*, calls the product an impulse, and equates it to change of momentum.

The expression of this operation is $Ft = M(v_1 - v_0)$, in which F must be a dynamic force which causes the change of momentum from Mv_0 to Mv_1. To put the equation into what is perhaps a more common form, we may multiply both members by $\frac{v_1 + v_2}{0}$, which will change it to a work equation. Thus, $Ft\left(\frac{v_1 + v_0}{2}\right) = \frac{M}{2}(v_1^2 - v_0^2)$, and in this, $\frac{v_1 + v_0}{2}t$ represents the distance through which the force, F, acts on the mass, M, and $\frac{M}{2}(v_1^2 - v_0^2)$ represents the difference of kinetic energies possessed by the mass, M, after and before the action of the force, F. In the case of the flow of water in a conduit, it does not seem reasonable to think of a difference between two static pressures acting on the fluid through any particular distance, and thus doing work on the water, any more than differences of static pressures on moving water in a pipe might be considered to be doing work on the water as it flows.

Table 3 contains the data of Bidone's experiments, as given by Professor Merriman, together with values of j computed by the various formulas.

TABLE 3.—Data of Bidone's Experiments, as Given by Professor Merriman.

d_1.	v_1.	Observed j.	j computed by Merriman's formula.	j computed by Engel's formula.	j computed by Unwin's formula.	j computed by Equation (A).
0.149	4.59	0.274	0.290	0.288	0.224	0.632
0.154	4.47	0.267	0.283	0.270	0.213	0.595
0.208	5.59	0.405	0.428	0.435	0.329	0.940
0.246	6.28	0.493	0.531	0.556	0.417	1.190

It is quite evident that Equation (A), which assumes no loss of head because of eddies, does not give correct values of j, and that it should contain a term which will express such loss of head. The term inserted by Professor Merriman was of the form used in the case of sudden expansion of section of pipe: whether this or some other expression should be used may probably not be decided from theoretical considerations alone. It is conceivable that some forms of the wave may result in very little disturbance by eddies, just as some forms of

Mr. Andrews. pipe enlargement produce very little loss of head, and in these cases the jump should be higher than in those cases where many eddies are produced.

Mr. Johnson. R. D. JOHNSON,* ESQ.—The speaker has been much interested in Mr. Kennison's able and valuable paper, and is glad to take part in the discussion.

Mr. Kennison calls attention, in a novel way, to a well-known phenomenon of Nature. His treatment of the subject is conclusive, so far as it goes, and leaves little or nothing to be said in criticism. The speaker has always regarded these "alternative" or complementary levels in a different way from that presented by Mr. Kennison, and it may be worth while to view the matter in a somewhat more commonplace light than through the medium of a cubic equation, two of the roots of which not only demonstrate the existence of "alternative" stages, but also determine them in relation to the quantity of water flowing and the fall of potential from the static level.

A casual reading of the paper might lead one to conclude that the depth of water in a flume is an unstable affair, and that, with slight provocation, it may flop to its "alternative" and continue indefinitely to flow at a different depth. This is a correct theoretical conclusion, neglecting friction, but it might be interesting to show, in a rough way, how much it is affected ordinarily by a consideration of "slope". It may be interesting, also, to point out the simple relation of one "alternative" stage to the other, which does not involve the cubic equation, although no other method can express the whole story so completely in one equation.

For the sake of this argument, let us deal, in imagination, with a flume so wide that d and r may be regarded as interchangeable quantities, and, merely for the sake of simplicity in illustration, let C, in the old Chezy formula, be considered constant through a reasonable range of conditions. Let the flume have a smooth bell-mouth entrance in which friction may be neglected. Let the water be regarded as flowing at a uniform depth, d_1, and with a velocity, v_1, the slope of the flume being s_1. Now, at some point well along in the flume, let the slope suddenly change to a greater one, s_2. This condition would naturally cause an acceleration of the water, and if the relation of s_1 to s_2 were just right, and a suitable submerged weir were placed at the transition point, the depth, d_1, on the slope, s_1, would not be altered, but the water would "jump" or suddenly slide into another régime of flow on the slope, s_2, at another uniform, though shallower, depth, d_2, and at higher velocity, v_2. This relation of the two depths is the one so completely expressed by Mr. Kennison in his cubic equation. It may be shown that this exact condition, as described, can

* New York City.

Mr. Johnson.

occur only when the two slopes bear a definite relation to each other, more or less independent of the quantity, Q, and when they are also inversely proportional to the cube of the respective depths, or directly proportional to the cube of the respective velocities. Also, that s_1 is less than $\frac{g}{C^2}$, and s_2 is greater than $\frac{g}{C^2}$, and that when each is made equal to $\frac{g}{C^2}$, and the submerged weir is finally removed, the flume will be carrying all the water that can possibly enter it, and the depth, at this time being equal to $\frac{v^2}{g}$, has no "alternative" and, therefore, cannot be made to "jump" to another value.

The relation of the velocities and depths on either side of the transition point, previously referred to, is expressed simply as follows (neglecting local eddy losses):

$\frac{v_2^2 - v_1^2}{2g} = d_1 - d_2$; also, $v_1 d_1 = v_2 d_2 = Q$ per unit width.

From these equations, we have,

$$v_1^2 (d_2 + d_1) = 2 g d_2^2 \quad \ldots\ldots(1)$$

and,

$$v_2^2 (d_2 + d_1) = 2 g d_1^2 \quad \ldots\ldots(2)$$

or,

$$d_1 = \frac{v_2^2}{4g} \left\{ 1 + \sqrt{1 + \frac{8 g d_2}{v_2^2}} \right\} \quad \ldots\ldots(3)$$

and,

$$d_2 = \frac{v_1^2}{4g} \left\{ 1 + \sqrt{1 + \frac{8 g d_1}{v_1^2}} \right\} \quad \ldots\ldots(4)$$

These equations express the relation of d_1 to d_2 for a given quantity of water (d_2 v_2 or d_1 v_1) flowing, and may be written equally well in terms of Q, eliminating v_1 and v_2.

The Chezy formula gives:

$$v_1^2 = C^2 d_1 s_1, \text{ and } v_2^2 = C^2 d_2 s_2.$$

Dividing one by the other, we have,

$$\frac{s_1}{s_2} = \frac{v_1^2 d_2}{v_2^2 d_1} = \frac{v_1^3}{v_2^3} = \frac{d_2^3}{d_1^3},$$

which expresses the necessary definite relation of the two slopes, in order that the quantity of water flowing at uniform depths may be the same in both cases. The relation of one slope to the other, necessary to maintain, indefinitely, the "alternative" water levels, may be obtained by combining these equations with Equations (3) and (4), eliminating the v and d, and becomes $\left(\frac{g}{C^2} \text{ being put} = s_m\right)$:

$$s_1 = \frac{1}{s_2^2} \left\{ \frac{4 s_m}{1 + (1 + 8 s_m \div s_2)^{\frac{1}{2}}} \right\}^3 \text{ less than or equal to } s_m,$$

Mr. Johnson.

and, $s_2 = \frac{1}{s_1^2}\left\{\frac{4\,s_m}{1+(1+8\,s_m \div s_1)^{\frac{1}{2}}}\right\}^3$ greater than or equal to s_m.

These particular slopes might appropriately be termed "alternative" slopes.

By inspection of Equation (1), it may be seen what takes place when s_1 is increased and s_2 is decreased, bringing them together and drowning out the "jump"; for then d_1 and d_2 become equal, and we have, calling the new common velocity, v_m, and the depth, d_m,

$$v_m^2 \times (2\,d_m) = 2\,g\,d_m^2, \text{ or } d_m = \frac{v_m^2}{g}, \text{ and } s_m = \frac{g}{C^2},$$

which might be termed the "natural slope" of a flume, because it represents the minimum slope which will carry away, at uniform depth, all the water which can be accelerated into it or be made to enter it. The depth of the water is twice the velocity head, and, therefore, the surface at the flume entrance drops one-half the depth in order to accelerate the water. As Mr. Kennison has pointed out, this condition obtains when the flume offers no restriction to the flow, and the maximum possible quantity is entering it; or, in this case, the point of control caused by the submerged weir has been entirely removed, and the slope evened up uniformly throughout its length.

If the distance from the still-water surface to the bottom of the flume, at the entrance, be called H, then $d_m = \frac{2}{3}H$, and $v_m = \sqrt{2\,g\,\frac{H}{3}}$, and $Q = d_m\,v_m = \frac{2\,H}{3}\sqrt{\frac{2}{3}\,g\,H} = 3.09\,H^{\frac{3}{2}}$, which is the natural formula for a smooth submerged weir, and also represents the quantity which requires a slope of $\frac{g}{C^2}$ to keep it moving at uniform depth, and expresses a stable condition of flow which has no "alternative".

The foregoing analysis falls far short of a rigid and logical mathematical discussion, and is intended only to point out some interesting physical relations which may furnish a side light on Mr. Kennison's work, even if it adds nothing to it.

The fact that C is not constant and that r is not equal to d will modify, of course, the numerical results derived for any particular case.

Lately,* there has been so much discussion of the mysteries of the hydraulic jump that the writer feels impelled to advance his own theory of the nature and magnitude of the losses involved, because he believes that the matter is capable of a more or less accurate analysis and should therefore be particularly interesting to those students of the subject who have searched in vain for an insight

* This part of Mr. Johnson's discussion was submitted subsequently by letter.

into Nature's method of determining a new water level following the so-called jump. Mr. Johnson.

In the discussions on this paper there appear many conflicting arguments, not only as to the possible magnitude of the losses, but even as to whether or not any loss exists—and it seems a proper time to lay down an exact method of determining these losses and to prove it by harmonizing the momentum and energy equations involved.

In the first place, it may be positively stated that, in a channel of uniform width, water cannot pass without loss from a lower to a higher level if the bottom remains flat. In other words, it may easily be proved essential that the lifting of the water surface be accompanied by a humping up of the bottom, if major eddy losses are to be eliminated. This will clearly appear from a brief mathematical discussion, but first it is desired to point out a fundamental law which pertains to the flow of water in a way perfectly analogous to its behavior with respect to solid bodies.

It is a well-known principle of impact that the sum of the momenta of two solid bodies cannot be altered by such bodies merely bumping into each other, and this is true, whether or not the impact results in a loss of energy; this law is commonly called the conservation of momentum, and is particularly interesting as applied to fluids because this persistence of the momentum law, in spite of energy or eddy losses, enables a comparison to be made between the momentum and energy equations which may disclose the inevitable eddy loss and determine the exact amount of it.

Now, in the case just referred to, of a change of water level to its higher alternative, theoretically without loss of energy, a comparison between the momentum and energy equations clearly shows the necessary existence of a force, F, which represents the tendency of the weir to slide up stream, and the necessary existence of the submerged weir is demonstrated in this, if in no other way, because the force cannot exist without the presence of the obstructing body.

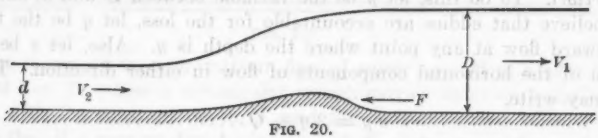

FIG. 20.

There are many other interesting ways of demonstrating the same thing, but they will be passed over as not particularly pertinent to the matter in hand.

Referring to Fig. 20, the energy equation is as follows, if there is to be no eddy loss:

$$\frac{v_2^2 - v_1^2}{2g} = D - d \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Mr. Johnson.

The momentum equation, which always holds good, whether or not there are energy losses, for unit weight of fluid and unit width of flume, is as follows:

$$\frac{D^2 - d^2}{2} - F = \frac{Q}{g}(v_2 - v_1) \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

which has been referred to by Dr. Unwin as a statement of the well-known physical law that force is equal to the rate of change of momentum.

It will be seen, from these two equations, remembering the relation, $d\,v_2 = D\,v_1 = Q$, that the value of F may be expressed in terms of other known quantities, and can never be zero, if Equation (1) holds good; therefore, Equation (1) cannot express the relation between the two depths and velocities unless a weir of proper form and dimensions is interposed.

Having now demonstrated the existence of the force, F, let us see what happens in the case of the hydraulic jump when there is no weir, and when, therefore, F must be zero.

It may be observed that by re-writing Equation (1) so as to include a certain friction or eddy loss, f, then the value of F in Equation (2) may become zero—and the new equations are:

$$\frac{v_2^2 - v_1^2}{2g} = D - d + f \quad \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and,

$$\frac{D^2 - d^2}{2} = \frac{Q}{g}(v_2 - v_1) \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

from which f may be determined as in the former case.

Now, although this statement of the matter really completes the whole story, it may be interesting to integrate the total eddy loss in a manner completely independent of Equation (3), and, having obtained its value, to show that its inclusion in Equation (3) makes this equation identical with Equation (4), thus demonstrating the whole matter *a fortiori*. To do this, let y be the variable between D and d, and, as we believe that eddies are accountable for the loss, let q be the total backward flow at any point where the depth is y. Also, let v be the mean of the horizontal components of flow in either direction. Then we may write,

$$v\,y = 2\,q + Q \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

and, from the momentum principle,

$$\frac{y^2 - d^2}{2} = \frac{Q}{g}(v_2 - v) \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

Solving $2\,q$ in terms of y, we have,

$$2\,q = \left(v_2 + \frac{g\,d^2}{2\,Q}\right) y - \frac{g\,y^3}{2\,Q} - Q \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Mr. Johnson.

Now, the power required to force the water, q, against the differential pressure, dy, is qdy; but, as the same quantity of water is returning on the other side of the eddy due to the same difference of head, dy, and under identical uniform conditions of impact, or heat losses, the total power required to keep these eddies in motion must be 2 qdy, and therefore the total lost power is expressed as

$$2\int_d^D qdy, \text{ and the friction head, } f = \frac{2}{Q}\int_d^D qdy.$$

Expressing q in terms of y, as above, and integrating we find,

$$f = \frac{D^2 - d^2}{2\,Q}\left(v_2 - \frac{g}{4\,Q}(D^2 - d^2)\right) - (D - d) \ldots\ldots\ldots (8)$$

and, if this is substituted in Equation (3) and the equation simplified as far as possible, we shall have Equation (4) as a result, thus harmonizing the equations of energy and momentum by recourse to a rational hypothesis of eddy loss.

Mr. Merriman.

MANSFIELD MERRIMAN,* M. AM. SOC. C. E.—Fig. 11 of Mr. Kennison's interesting paper appears to indicate that the hydraulic jump is caused by a slight obstruction or irregularity in the bed of the channel just below the toe of the jump; this figure also shows an upward spurt of the water at the top of the jump. The speaker, having seen jumps formed in a rectangular trough, is able to affirm that they may occur without any obstruction near the toe, and that usually there is no upward spurt at the top. Undoubtedly, a so-called jump may occur when a considerable obstruction exists in the bed of the channel and perhaps such was in the mind of the author when he prepared Fig. 11. The true hydraulic jump, however, is of a different character.

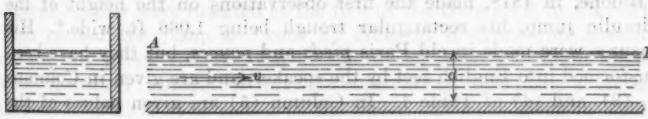

FIG. 21.

The theory of the non-uniform flow of water applied to a case like that of Fig. 21, where a rectangular trough carries water on a uniform slope, with the constant depth, d, and the constant mean velocity, v, shows that if a gate or dam be inserted at E, a change in the surface, $A\,E$, will take place in one of two ways. Fig. 22 shows the way which occurs when v is less than $\sqrt{g\,d}$, where g is the acceleration of gravity. Here the water surface is convex to the bed of the channel and extends a long distance up stream. This is the common case of backwater

* New York City.

Mr. Merriman.

which occurs in streams when the original surface of the water is raised by the construction of a dam or bridge piers.

Fig. 23 shows the second case, where the mean velocity, v, is greater than $\sqrt{g\,d}$, and here the true hydraulic jump is formed. From A to B the water is flowing with the uniform depth, d, at B the depth suddenly increases and shortly after reaches the greater depth, D, the surface of the water from B to E being concave to the bed of the channel. The distance, $E\,B$, from the dam back to the jump depends on the velocity, v, only; when v is only slightly greater than $\sqrt{g\,d}$, the distance, $E\,B$, is large; when v is very much greater than $\sqrt{g\,d}$, the distance, $E\,B$, may be quite small; but, wherever the jump may be formed, the depth, D, is theoretically always the same for the same velocity, v, and the same depth, d.

FIG. 22.

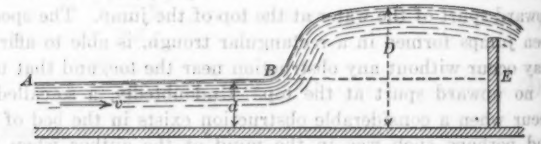

FIG. 23.

Bidone, in 1818, made the first observations on the height of the hydraulic jump, his rectangular trough being 1.066 ft. wide.* His measures were made in old Paris *pieds* and *pouces*, but they have been transformed into English feet by the speaker, and are given in Columns (2), (3), and (4) of Table 4. In Column (5) are given values of the ratio, $\frac{v}{\sqrt{g\,d}}$, as computed by the speaker, and in Column (6) are values of the lost head, computed from the expression,

$$h' = \frac{v^2 - V^2}{2\,g} + d - D,$$

in which V, the velocity corresponding to D, is found from $V = \frac{v\,d}{D}$, while g has been taken as 32.19 ft. per sec. per sec., this being the value for Paris, where the observations of Bidone were made.

In 1894, a number of observations were made at Lehigh University, by Mr. Robert Ferriday, in the preparation of a graduating thesis. An abstract of this thesis was published,* but, as it gives no results of the observations, it seems best to put them on record here, since the work was done under the writer's supervision. Mr. Ferriday's trough was 0.66 ft. wide and was laid on various slopes so as to produce different velocities. The depth in each observation was determined from the mean of three measures, and the velocities were found by measuring the water caught in a barrel in a given time. Dams of different heights were inserted at the foot of the trough (E in Fig. 23), which caused the jump to occur at different distances up stream; but, for any given velocity, the height of the jump was found to be closely the same. Altogether forty-six observations were made at eleven different velocities. The results of the eleven series are given in Table 5, in Columns (3), (4), and (5); and Columns (6) and (7) give the computed values of the ratio, $\frac{v}{\sqrt{g\,d}}$, and the head, h', lost in making the jump. In these computations, the value of g for Lehigh University has been taken as 32.16 ft. per sec. per sec.

These observations on the height of the hydraulic jump are all that are known to the speaker, except those made by Darcy and Bazin in 1856.† They give several series of observations made in a rectangular timber conduit, 1.99 m. (6.53 ft.) wide. In the series

* *Engineering News*, July 11th, 1895, Vol. 34, p. 28.

† "Recherches Hydrauliques" (Paris, 1865), pp. 284–292.

Mr. Merriman.

numbered 89, 90, and 91, the jump was quite ill-defined on account of the slight excess of v over $\sqrt{g\,d}$, the ratio of the former to the latter being from 1.1 to 1.3. For Series 92, the ratio, $\frac{v}{\sqrt{g\,d}}$, was between 1.5 and 1.9, and several characteristic jumps were obtained. All observations made by Bidone, however, have values of this ratio ranging from 2.0 to 2.3, and in six of Ferriday's observations the ratios are from 3.1 to 3.9. It appears unnecessary to give the observations of Darcy and Bazin here, as they may be readily consulted in their book. The speaker is inclined to the opinion that good characteristic jumps will rarely be formed unless the velocity, v, is greater than $2.0\ \sqrt{g\,d}$. The great variation in the values of the lost head given in the last columns of Tables 4 and 5, shows how difficult it is to make precise measurements on the height of the hydraulic jump; five of these values are negative, which indicates that the corresponding observations are probably of little value.

TABLE 5.—FERRIDAY'S OBSERVATIONS ON HYDRAULIC JUMPS.

Mr. Ferriday also noticed the fact that at the toe of the jump there was no horizontal velocity along the bottom of the trough, as balls of putty placed in the trough at the upper end moved along the bottom until they reached a point just below the toe of the jump, where they stopped. This indicates that probably the lower strata of water turn upward in order to make the jump; if so, it may be inferred that a jump formed near the foot of an apron of an ogee dam will be very advantageous in preventing scour.

Two formulas for the height of the jump are given by Bidone in his paper of 1819, and four or five others have been derived by later writers. All these formulas are imperfect on account of the neglect of the fall between the sections at d and D and other ele-

ments difficult to include, and also, in some cases, on account of defective reasoning. The formula of Belanger, later adopted by Rühlmann and by Weisbach, assumes that no loss of head occurs in forming the jump, and hence values computed from it are considerably in excess of observed values. Nearly all formulas, in fact, give computed values higher than those observed. To derive a reliable formula for the height, D, from observed values of d and v, it seems necessary that coefficients should be introduced, which are derived from the study of observations. No doubt this will be done in time, and, perhaps, the observations previously given may aid in deriving such coefficients. Mr. Merriman.

The author's use of the term "hydraulic gradient" seems to be unfortunate, and does not agree with that generally used. When a number of piezometers are placed on a pipe, the line connecting the water levels in them is the hydraulic gradient; when water flows in an open channel, its surface is the hydraulic gradient. The term "energy gradient" better applies to the curve formed by successive values of the author's H, as this is the sum of the pressure head and the velocity head.

The author deserves much credit for preparing this interesting paper, as it deals with a subject which has been rarely discussed. Observations like those made by Mr. Ferriday, in 1894, can easily be conducted in any hydraulic laboratory, and it is hoped that further experimental work may be done in this direction. One who has seen the true hydraulic jump, under the conditions shown in Fig. 23, can never forget it, as it violates the impressions which he has formed by observing the usual backwater case of Fig. 22. In all hydraulic laboratories for the instruction of students it would be well to have the hydraulic jump exhibited occasionally.

E. G. WALKER,* Assoc. M. Am. Soc. C. E. (by letter).—The problem of the "hydraulic jump", or, as it is frequently named, the "standing wave", is one which has been before irrigation engineers for many years. The phenomena accompanying the formation of a standing wave were investigated by the engineers of the Government of India in the early days of river control and irrigation works in that country. As the author states, one may look in vain in the generality of textbooks on hydraulics for a proper discussion of the subject, but the writer wishes to point out one important exception which, apparently, has not been brought to Mr. Kennison's notice. In his article on "Hydraulics" in the Ninth Edition of the Encyclopædia Britannica, Dr. W. C. Unwin, at that time Professor of Hydraulic and Mechanical Engineering at the Royal Indian Engineering College, Cooper's Hill, developed the theory of the standing wave on a rational basis, and Mr. Walker.

* Hull, England.

Mr. Walker.

worked out the conditions under which the phenomenon becomes possible.* This is the most complete exposition of the subject known to the writer. The article has been revised for the present (Eleventh) edition of the Encyclopædia.

The author, in Section 2 of the paper, starts off his theory with a postulate that "there are certain controlling sections" at which "for the given head and channel depth, the discharge is a maximum." Some further explanation of this statement appears to be desirable, for as soon as a definite régime of flow exists in a channel, no matter how complex the conditions of flow may be, the discharge at all sections must be the same, or there would be discontinuity of flow at some point. Would it not be a truer statement of the case to say that there exists a "critical stage" in the flow, dependent on the friction, form and slope of the channel bed, and the velocity of the stream, at which the water level will change from the lower to the higher?

The statement in the last paragraph of Section 2 is important. Considerable misconception has arisen owing to the incorrect application of formulas for the loss of head by sudden expansion to conditions to which they are not applicable. The sudden transition from one state of equilibrium to the other, found in the hydraulic jump, involves no energy loss, except such as is due to the fact that water is not exactly the theoretical fluid it is assumed to be. There is no reason for assuming, without proof, that results applicable to flow in pipes should be applied without change to open-channel flow under atmospheric pressure. It has been shown experimentally that such assumption is incorrect.

Although the author discredits the "sudden expansion" theory as originally propounded, he does not offer any modification to replace it. On the principle so often used in hydraulic calculations, namely, that force exerted is equal to the rate of change of momentum, Dr. Unwin develops, in the article previously mentioned, a formula for the depth of water after the jump, which is free from incorrect assumptions. His formula, in the notation of the paper, is

$$d_2 = \sqrt{\left\{ \frac{2\,V_1^2}{g}\,d_1 + \frac{1}{4}\,d_1^2 \right\}} - \frac{1}{2}\,d_1 \qquad \ldots\ldots(1)$$

as compared with,

$$d_2 = \sqrt{\frac{2\,V_1^2}{g}\,d_1} \qquad \ldots\ldots(2)$$

the formula of the "sudden expansion" theory.

The subject has recently been investigated experimentally by Professor A. H. Gibson, of Dundee, Scotland. His experiments are described in a paper entitled "The Formation of Standing Waves in

* Vol. XII, pp. 499–502.

an Open Stream."* He applies Equations (1) and (2) to his experimental results, and also to a series of experiments of Messrs. Darcy and Bazin, and shows that, for his own experiments, whereas Equation (2) gives discrepancies of from 3 to 23% excess in the values of d_2, the range of variation using Equation (1) is only from $-4\frac{1}{2}$ to $+3\frac{1}{2}$ per cent. The results in the case of the Darcy and Bazin experiments are more startling, the differences being, for Equation (2), from 22 to 77%, and for Equation (1) from — 3 to + 3 per cent. By allowing for the variation of velocity over the cross-section of the stream, the depth calculated from Equation (1) can be brought still more closely to approximate to the measured depths. Mr. Walker.

EDWARD W. BUSH,† M. AM. SOC. C. E. (by letter).—Figs. 24 to 28 may be of interest to those studying the hydraulic jump below ogee-faced dams, where the toe is some distance up from the bed of the Mr. Bush.

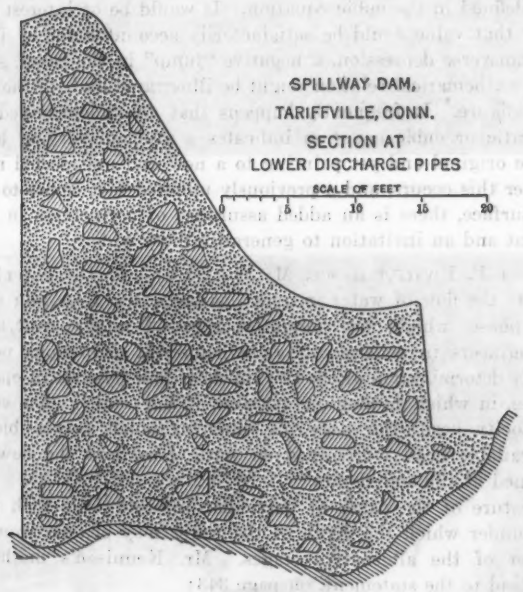

FIG. 24.

stream. This dam is on the Farmington River, at Tariffville, Conn., and was completed late in the season of 1899, by the Hartford Electric Light Company. On February 14th, 1900, when the flood pictures

* *Minutes of Proceedings*, Inst. C. E., Vol. CXCVII, p. 233, *et seq.*

† Hartford, Conn.

Mr. Bush. (Figs. 26, 27, and 28) were taken, the flood height was 9.5 ft. above the crest, and 1.5 ft. above the bulkhead.

Fig. 24 shows the section of the dam at the lower discharge pipes; Fig. 25 is a construction view on September 24th, 1899; and Figs. 26, 27, and 28, show the 9.5-ft. flood passing over the dam.

The jump was quite irregular in action, and surged up and down stream over a considerable distance. The height of the jump also varied greatly.

Fig. 25 shows that the river bottom was quite irregular below the dam. This, no doubt, helped to cause the irregularities in the jump. No damage was caused by the flood. The bulkhead wall was raised a few feet to prevent future floods from over-topping it.

Mr. Dunham. H. F. DUNHAM,* M. AM. SOC. C. E.—In the early part of this discussion there was a reference to a value that was mysterious—a third root undefined in the cubic equation. It would be of interest to know whether that value could be satisfactorily accounted for by introducing a transverse depression, a negative "jump" in the canal, so that a further mathematical relation might be illustrated by both the analysis and the figure. It frequently happens that an undetermined root in a quadratic or cubic equation indicates a problem varying but little from the original and yet pointing to a new and unexpected meaning. Whenever this occurs, and a previously unnoted fact comes to light or to the surface, there is an added assurance of correctness in the first statement and an invitation to generalize more widely.

Mr. Ewald. ROBERT F. EWALD,† ASSOC. M. AM. SOC. C. E. (by letter).—With respect to the flow of water in open channels, Mr. Kennison discusses certain phases which have heretofore received rather scant attention from engineers in general. His mathematical deductions permit of the ready determination of the two limits of flow possible in open channels; one, in which as much as possible of the total head is converted into velocity head; the other, in which as much as possible of the total available head is retained as static head and the flow is still maintained at the stated rate.

A feature of the paper of particular interest deals with the conditions under which the depth of the water may change from one to the other of the alternative stages. Mr. Kennison's mathematical studies lead to the statement, on page 343:

"The jump proper, or the passing from the lower to the upper stage, does not involve energy losses, except incidentally, and it is doubtful if the ordinary formula for loss by 'sudden expansion' applies in this case."

* New York City.

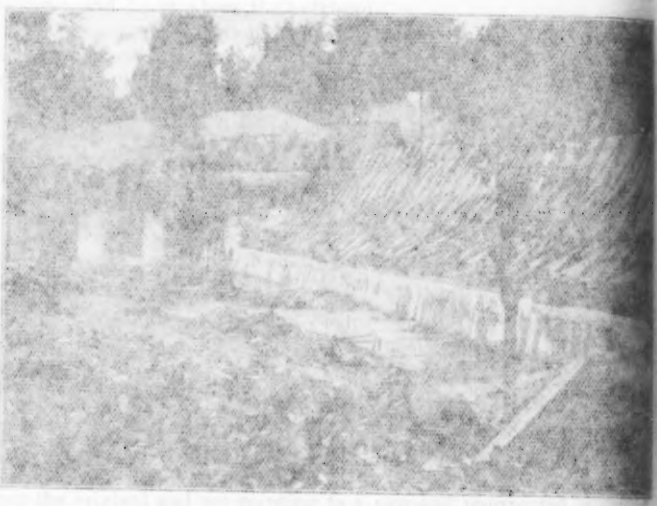
FIG. 25.—DAM AT TARIFFVILLE, CONN., UNDER CONSTRUCTION SEPTEMBER 4TH, 1899.

FIG. 26.—TARIFFVILLE DAM, WITH 9.5-FOOT FLOOD.



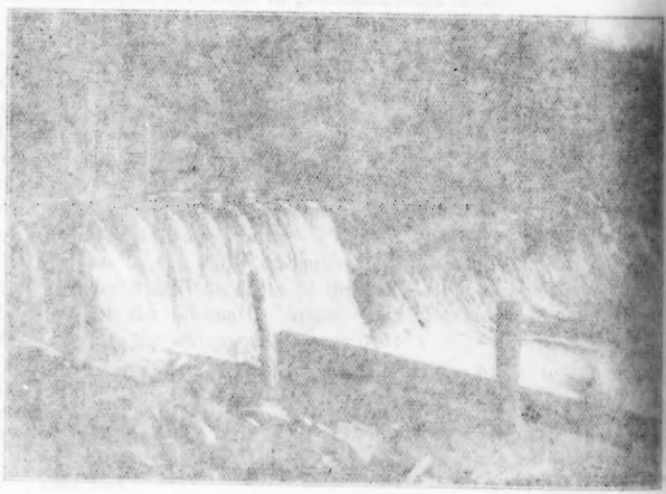


FIG. 27.—TARIFFVILLE DAM, WITH 9.5-FOOT FLOOD.

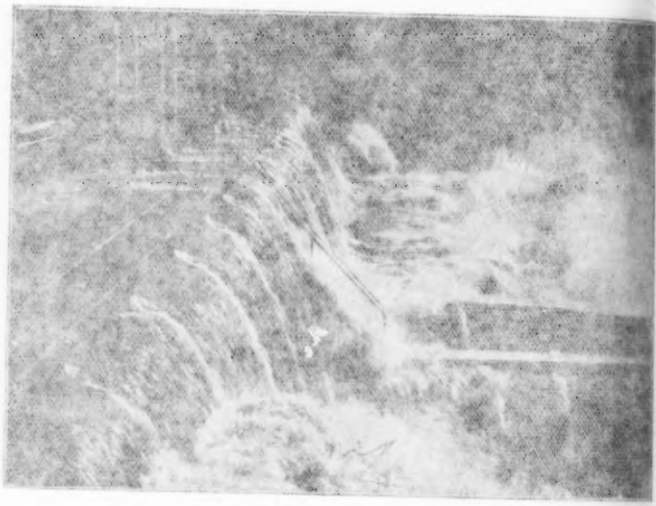
FIG. 28.—TARIFFVILLE DAM, WITH 9.5-FOOT FLOOD.



Mr. Ewald.

This statement may need modification, and perhaps should be strictly limited to rises occurring under conditions governed by actual external controlling sections, as defined in the paper, because there is ample evidence to show that, in channels of uniform cross-section and gradient, rises may be produced which are accompanied by considerable inherent energy losses, which losses are independent of channel conditions, and apparently conform to some law not yet definitely established. These energy losses, when very high velocities are concerned, amount to a very large percentage of the original kinetic head, and become a factor of the greatest importance. If the existence of inherent energy losses is admitted, then the jump, in a sense, becomes a control, because, within it, the hydraulic gradient is brought down to such a position as to permit of the change in levels. In order

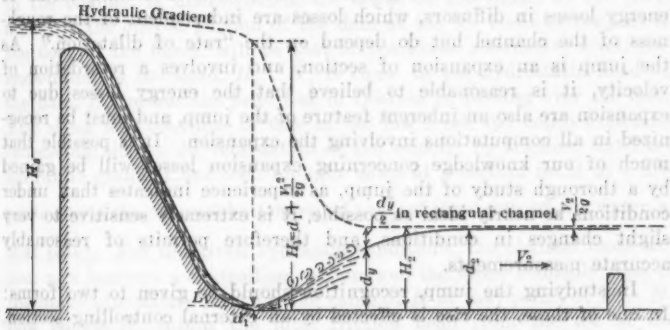


FIG. 28.

to render the actual conditions clearer, it will be necessary to refer to Fig. 29, which shows the ideal jump as developed at the toe of an overflow dam. An essential condition in this case is that the obstruction, or weir regulating the height of the jump, be far enough down stream to permit the water, after passing through the jump, to attain uniform flow parallel to the bottom before passing over the weir. Due to the inherent energy losses occurring in the water as it rises, the hydraulic gradient has been brought down from its high level at section d_1 to the much lower level at d_y. At the point, d_y, where the gradient becomes nearly level and the depth of the water in a rectangular channel is two-thirds of the distance from the bottom of the channel to the hydraulic gradient, we have a condition in which the water is flowing, according to Mr. Kennison's theory, at the lower of two corresponding alternative stages for the total head, H_2. The higher stage for this value of H_2 is that existing at the section, d_2,

Mr. Ewald.

and the water rises to this level from d_y without further loss of energy. Actually and theoretically, we have a condition then in which, discussing the jump as a whole, there is an inherent loss of energy, causing the drop of the hydraulic gradient and the establishment of a controlling section within the jump. The remainder of the rise is effected without considerable energy loss.

The writer includes the term "theoretically" in the previous paragraph, because he hopes that, ultimately, the science of hydromechanics will be advanced so that it will be possible to determine and explain, with a reasonable degree of accuracy, the losses of energy due to expansion, much in the same way as the electrical engineer is able to measure and foretell the effects of self-induction in alternating currents. Mr. F. zur Nedden, in his paper on "Induced Currents of Fluids,"* recognizes the existence of certain forms of energy losses in diffusors, which losses are independent of the roughness of the channel but do depend on the "rate of dilatation." As the jump is an expansion of section, and involves a retardation of velocity, it is reasonable to believe that the energy losses due to expansion are also an inherent feature of the jump, and must be recognized in all computations involving the expansion. It is possible that much of our knowledge concerning expansion losses will be gained by a thorough study of the jump, as experience indicates that, under conditions as nearly ideal as possible, it is extremely sensitive to very slight changes in conditions, and therefore permits of reasonably accurate measurements.

In studying the jump, recognition should be given to two forms: In one of these, the rise is effected by an external controlling section, and no energy losses occur, aside from those due to channel friction and a certain minor form of impact loss corresponding to that occurring in solid bodies and expressed by the term, $(1 - e)^2 \frac{(V_1 - V_2)^2}{2} M$, in which e is the coefficient of restitution. It is suggested that this form of the jump be designated as the "standing wave", as the term "wave" does not necessarily involve the idea of energy loss. (It will be noted that Mr. Groat has used the term "standing wave" in his discussion.) The second type of rise occurring in channels of uniform cross-section, involving certain inherent energy losses, and forming within itself the controlling section, may be designated as the "hydraulic jump", as the term has been used so frequently in connection with the discussion of energy losses at the toes of overfall dams, which cases usually involve rises of the type under discussion.

The Standing Wave.—The standing wave is formed when channel and external controlling sections are adjusted so as to produce flow

* *Proceedings*, Am. Soc. C. E., for August, 1915.

in accordance with the conditions discussed by Mr. Kennison and Mr. Groat, and constitutes a type of rise which has been observed frequently. Examples of the standing wave are given by Mr. Kennison in Figs. 5, 7, and 8.* The flow over submerged weirs under certain conditions affords the most and best examples. The standing wave has been so ably handled by the author and those following him, that no further discussion will be attempted. Mr. Ewald.

The Hydraulic Jump.—At the risk of being charged with presenting matters much too elementary, a brief discussion will be given of the action of the hydraulic jump under conditions as nearly uniform and ideal as it is possible to obtain. An ogee type, straight-crested, spillway dam is constructed in an open rectangular flume of dressed lumber. The cross-section of the flume is uniform, and the bottom is level. If water is allowed to pass over the dam, and the flow in the channel is unobstructed, the depth of the water, at the point at which the curved portion of the dam at the toe becomes tangent to the floor of the flume, will be that of the lower alternative level, corresponding to the head, H_1. H_1 is equal to the hydrostatic head on the dam, H_s, minus the head lost in friction in passing over the dam. The water will continue to flow at the low level, the depth gradually increasing, due to the retardation of the velocity by friction, until the hydraulic gradient has been brought down at a certain point to a distance above the channel bottom equal to $\frac{3}{2}$ of the depth of the water at that point. For the given hydraulic conditions, the channel cross-section now becomes a controlling section, and the water suddenly rises to the upper alternative level for the value of H at that point, or H_2. H_2 now equals H_1 minus the total friction head from the toe of the dam to this point. Where the velocity is high, a considerable length of the flume is required to lower the hydraulic gradient to the requisite height.

If, at a short distance toward the dam from the point where the rise is developed, a slight obstruction is placed across the channel, it is probable that sufficient energy will be absorbed in impact to bring the gradient down to the requisite height, and the wave will move up stream to or near the obstruction. Now, if slight increments are made to the depth of the water, the crest of the rise will move toward the dam, and finally the initial point may be brought exactly to the toe of the dam. The conditions are now as shown in Fig. 29. The obstruction in itself does not develop the energy losses, and, as the velocity of the water over the channel bottom has been decreased, the effect of friction is decreased materially. The losses necessary to bring the gradient down to the position shown are developed within

* One is also shown in the central portion of Fig. 358 in the first edition of Mead's "Water Power Engineering."

Mr. Ewald.

the rise. Experiments of this character have been performed frequently, and there seems to be a definite relationship between the velocities, V_1 and V_2, and the depths, d_1 and d_2; hence the conclusion that the energy loss is inherent, and is probably a determinable quantity.

A few figures will be presented in order to indicate the extent of observed losses in the jump. On a dam, constructed in general according to Fig. 29, 4.08 ft. high above the floor of the flume, with a discharge of 0.580 cu. ft. per sec. per lin. ft. of crest, the depth of the water at d_2 was found to be 0.583 ft., and, with a Pitot tube, the velocity head at d_1 was found to be 3.17 ft., corresponding to a velocity of 14.29 ft. per sec. From the discharge, estimated from the head on the dam, which had been calibrated previously by a sharp-crested, suppressed weir, the depth of water at d_1 was estimated to be 0.041 ft. The value of H_1, then, must have been $3.17 + 0.041 = 3.211$ ft. For this value of H_1, according to Mr. Kennison, the lower level depth should be 0.039, which checks out reasonably well with the observed figure, and the upper level depth would have been 3.2103. The obstruction, a movable weir crest, was placed 18 ft. down stream from the toe of the dam. Without any change in the character of the channel, at the point where the expansion occurred, an actual loss of head, amounting to $(3.17 - 0.155) - (0.583 - 0.041) = 2.473$ ft., took place within a distance in which, previously, not more than 0.01 had occurred, with a velocity of 14.29 ft. per sec. The loss amounted to 82.3% of the difference in velocity heads between d_1 and d_2, and 79.6% of the original velocity head.

Many of those who have read Mr. Kennison's paper, no doubt have looked up the description of the Truckee main canal chute, and read the account of the jump formed therein. Judging from the illustrations accompanying the description, at least 15 ft., or about 85% of the original velocity head, was absorbed in the jump. As this occurred in a relatively smooth channel, it is extremely difficult to conceive of any form of channel friction or other form of "incidental loss" that would account for the great loss of head that actually developed.

The various pictures of dams in action, in the paper and in the discussions, give good visual evidence of the existence of large energy losses. In the case of the Bassano Dam, the fact has been pointed out by Mr. Muckleston that channel conditions, as influenced by the presence or absence of irregularities designed to increase impact losses, have relatively insignificant influence on the amount of head absorbed.

Where the jump is formed in a regular channel, on smooth surfaces, similar to the conditions for the dam in the flume, as just

Mr. Ewald.

discussed, casual observation and simple tests reveal several interesting features. The quantity of water undergoing actual retrograde movement toward the dam is relatively small as compared with the total quantity flowing. A small quantity flows down the surface of the rise sloping toward the dam, and produces the appearance of considerable agitation. Pitot tube tests show that the velocities are almost always down stream, and decrease fairly uniformly. The absorption of energy, under these conditions, is accompanied by a minimum of sound, the sensation on the observer being that gained by listening to a good motor running at full load under the most efficient conditions, after the starting noise has subsided. The general impression is that fairly complete absorption of energy is taking place, without much influence on the channel. These remarks, of course, do not apply to channels in which irregularities of any considerable extent are to be found.

There is serious need of reasonably exact knowledge concerning the nature and extent of the energy losses involved in the jump. In connection with the design of dams, the jump, in itself, establishes the minimum hydraulic conditions under which the requisite expansion of section and reduction of velocities to safe limits may be accomplished. The position of the jump must be controlled at all stages, so that the expansion is effected on smooth aprons of material which will resist the initial velocity. This is true, not only of low dams and waste-ways, but also of high dams, in many of which the overfall velocities pass the limits of those which may be safely carried by the hardest rock. The necessity and dimensions of such aprons are matters which should be capable of ready determination while the dam is being designed. At present, there are no accepted rules or hydraulic formulas which will enable one to assert positively, in all cases, that the existing normal channel depth of water is or is not sufficient for the formation of the jump at the toe of the dam. Fortunately for most dams, the natural channel depths down stream from the dam are sufficient to maintain depths greater than necessary, and also, in most cases, the rise of the water below the dam is at a greater rate than on the crest, usually producing more stable conditions at the extremely high discharges than may be found at the intermediate stages. A particular case of this kind is pointed out by Mr. Muckleston.

It has been assumed, generally, that the mathematical expression for the lost head in the jump has the general form, $\frac{(V_1 - V_2)^2}{2g}$. This form probably is not far from the truth, when it is remembered that the work involved in retarding the velocity of a moving body

Mr. Ewald.

from V_1 to V_2 ft. per sec., according to the principles of mechanics, has the general form, $\frac{M}{2}(V_1 - V_2)^2$. As the losses are partly effective in retarding the velocity of the water passing through the jump, it seems probable that the general expression for the loss will be a term of the form, $\frac{(V_1 - V_a)^2}{2g}$, in which V_a is to be considered as the average velocity that the water would have, assuming that the losses alone are effective in retarding the velocity. The final value of the velocity, V_2, has been used by several writers for V_a, but this, apparently, is inconsistent with the original assumption, as part of the reduction to the final velocity, V_2, is effected, during the vertical component of the path traversed by each particle of water, in direct action against the force of gravity, and the energy represented by this process reappears as static head. This is not lost head. The term, $\frac{(V_1 - V_a)^2}{2g}$, may also be expressed in the form, $\frac{\left[V_1 - (\sqrt{2gh'} + V_2)\right]^2}{2g}$, in which $\sqrt{2gh'}$ is to be considered as the average velocity retarded in rising against the "force of gravity" alone through the height, $d_2 - d_1$. The correct evaluation of the term, $\sqrt{2gh'}$, is necessary in order to obtain the true general equation for the jump. The true relation of the values of V_a or $\sqrt{2gh'}$ to the other factors entering into the jump, such as V_1, V_2, d_1, or d_2, has not yet been established. The limiting value of $\frac{(V_1 - V_a)^2}{2g}$ apparently is an expression of the form $\frac{(V_1 - k\,V_2)^2}{2g}$, in which $k\,V_2$ is to be considered as the velocity at that point in the jump at which the depth of water bears such a relationship to the height of the hydraulic gradient that the further rise of the water to the higher level down stream from this point is effected without further loss of energy, in accordance with Mr. Kennison's theory. This limiting value seems to be closely approached in jumps formed in water flowing at very high velocity, say, 10 ft. per sec. or greater. Assuming for the present that the actual value is the same as the limiting value, the following equations may be developed:

Neglecting friction losses, Bernouilli's theorem for the conditions shown in Fig. 29, may be written,

$$\frac{V_1^2}{2g} - \frac{V_2^2}{2g} - (d_2 - d_1) = \frac{(V_1 - k\,V_2)^2}{2g}$$

$$\frac{V_1^2}{2g} - \frac{V_2^2}{2g} - (d_2 - d_1) = \frac{V_1^2 - 2\,V_1\,k\,V_2 + k^2\,V_2^2}{2g} \quad \ldots\ldots(1)$$

Mr. Ewald.

Collecting terms:

$$\frac{2\,V_1\,k\,V_2}{2\,g} - (1 + k^2)\,\frac{V_2^2}{2\,g} = d_2 - d_1.$$

We also have the equation:

$$V_1\,d_1 = V_2\,d_2$$

and

$$\frac{d_2}{d_1} = \frac{V_1}{V_2} = \text{to } n \text{ (assumed)}.$$

Then, in the foregoing equation:

$$\frac{2\,V_1^2\,k}{2\,g\,n} - (1 + k^2)\,\frac{V_1^2}{2\,g\,n^2} = (n - 1)\,d_1$$

$$\frac{V_1^2}{2\,g}\left(\frac{2\,k}{n} - \frac{(1 + k^2)}{n^2}\right) = (n - 1)\,d_1$$

$$\frac{V_1^2}{2\,g} = \left(\frac{n - 1}{\dfrac{2\,k}{n} - \dfrac{(1 + k^2)}{n^2}}\right) d_1$$

$$\frac{V_1^2}{2\,g} = \left[\frac{n^3 - n^2}{2\,k\,n - (1 + k^2)}\right] d_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Also:

$$\frac{n^3 - n^2}{2\,k\,n - (1 + k^2)} = \frac{V_1^2}{2\,g\,d_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2_1)$$

In a rectangular section in which the hydraulic gradient is but little higher than the surface of the water at d_2, the velocity at d_y is approximately $\frac{3}{2}\,V_2$ and the value of k is $\frac{3}{2}$. Substituting this value in Equation (2), we get:

$$\frac{V_1^2}{2\,g} = \left(\frac{n^3 - n^2}{3\,n - 3.25}\right) d_1,$$

which is the approximate expression for the jump in open rectangular channels, provided V_2 is so small that it makes k equal $\frac{3}{2}$ nearly. Values of the expression, $\frac{n^3 - n^2}{3\,n - 3.25}$, for values of n up to 20, have been plotted as a curve in Fig. 30.

The application of this equation to a few examples of the jump will be given. One example, in which $V_1 = 14.29$; $d_1 = 0.041$; $V_2 = 1.00$; and $d_2 = 0.583$, has already been mentioned. For this case,

$$\frac{V_1^2}{2\,g\,d_1} = \frac{n^3 - n^2}{3\,n - 3.25} = \frac{3.17}{0.041} = 77.4.$$

Mr. Ewald.

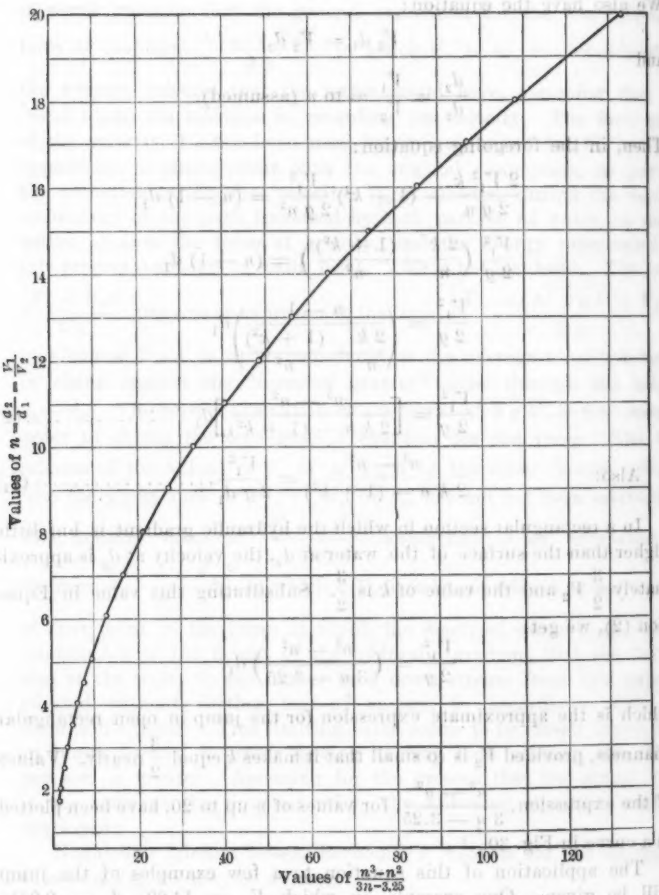

FIG. 30.

Referring to the curve, the value of n is found to be about 15.2, and nd_1 becomes $15.2 \times 0.041 = 0.624$. The observed value of d_2 was 0.583. Mr. Ewald.

The jump in the concrete chute of the Truckee Canal was not formed in a channel with a level bottom, and the equation is not exactly applicable. However, if it is assumed that the velocity of V_1 was 34 ft. for the limiting discharge of 90 sec-ft., d_1 would be 0.265, and

$$\frac{V_1^2}{2gd_1} = \frac{n^3 - n^2}{n - 3.25} = 68,$$

for which $n = 14.3$ and $nd_1 = 3.79$. The actual difference in elevation of the initial point of the jump on the slope and the surface of the water below the jump apparently is very close to 3.5 ft.

The limited data, based on Bidone's experiments, at present available to the writer, do not check the equation given, the value of n, as derived from the curve, being only 2.46, though the actual value was almost exactly 3.0 for the particular example quoted by Mr. Kennison. Bidone's experiments were made in channels having slopes of about 0.02, and the actual difference in elevation of the surface of the water at the initial point of the jump and the crest of the rise probably was considerably less than the value $(d_2 - d_1)$ used in deriving the equation. Also, as the value of V_2 was comparatively large, the value of k would differ from $\frac{3}{2}$ by a considerable amount. If the conditions of the experiments were actually as shown in Fig. 11, another reason for the discrepancy would be found in the fact that the obstruction forming the jump was nearly under the crest and deflected all the water upward toward the gradient to an extent sufficient to cause the obstruction, regardless of its small size, to act as an external controlling section, and form a rise more in the nature of the standing wave. Equation (2) will apply strictly only to those conditions in which the crest of the jump is far enough up stream to permit the water to attain a condition of uniform parallel flow before passing over the obstruction. The function of the latter is simply to maintain a depth of water sufficient to permit the minimum conditions under which internal absorption of energy can take place.

The flow of water over arched dams into channels of varying depth introduces complications necessitating individual study for each case. Observation indicates that in a dam having a uniform depth of water over the crest, the jump will be pushed farthest down stream in the shallower sections. This indicates that, instead of treating the cross-section as a whole, or averaging the depths, the entire cross-section should be divided into sections having bottoms of nearly uniform elevation, and treating each section as a rectangular channel, paying

Mr. Ewald. particular attention to the values of V_1 and d_1 for the water entering those sections.

In summing up, it appears that there are certain types of rise in open channels in which there is little or no loss of energy, and that there are other types in which the inherent energy loss is very great. The latter type is of great importance to the designer of dams, waste-ways, etc., and merits much additional study.

Mr. Cornish. L. D. CORNISH,* M. AM. SOC. C. E. (by letter).—This paper and the discussions thereon are extremely interesting, and form a valuable addition to the disseminated knowledge of hydraulics. The writer regrets that lack of time prevents him from preparing a satisfactory discussion, but the facts regarding two cases which he has observed will be submitted, and may be of interest in connection with Part 6 of the paper.

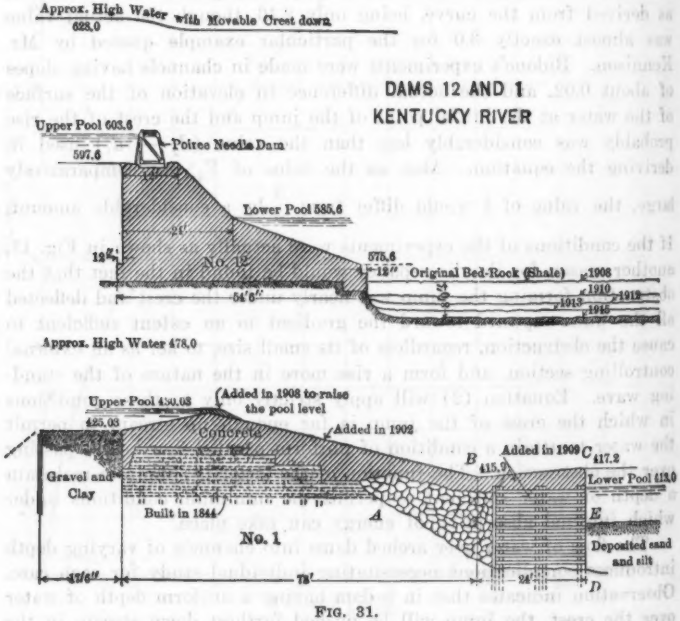

FIG. 31.

Fig. 31 shows sections of two dams which are now in operation on the Kentucky River. Dam No. 12 was put into operation in 1908, and is founded on a laminated shale which, *in situ* or in large masses,

* Cincinnati, Ohio.

Mr. Cornish.

was apparently hard and durable, although small pieces, when thoroughly dried out and subsequently immersed in water, would rapidly break up into a finely-divided condition like mud. During periods of high water the movable crest is lowered, and the water surface may be anywhere between the limits shown. As indicated by the profiles, the water is gradually eroding the shale, which had to be broken up by blasting during construction excavation, and the eroded material has formed a bar about 150 ft. below the dam. The surface of the bar consists of large pieces of shale, many of which are approximately 3 by 7 ft. and from 6 to 8 in. thick, and the entire bar has been formed by material eroded from just below the toe of the dam.

Dam No. 1, 4 miles above the point where the river empties into the Ohio, is typical of several other dams above it. It was originally a timber crib structure, built in 1844, and was capped with concrete as far as *B* in 1902. The water scoured out the river bed to a depth of 20 ft. at *D*, and undermined and carried away the crib and concrete cap as far back as *A*, for a width of 150 ft. In 1909 this damage was repaired by constructing the concrete-capped rip-rap fill and crib, since which date the erosion has ceased and fine material (*D E*) has been deposited below the crib. The approximate depth of this deposit is 12 ft., but it varies considerably during a season of frequent rises.

The absence of further erosion is attributed entirely to the apron. the inclined surface of which is typical of many movable and fixed dams on the Ohio River and its tributaries, and the construction of a similar crib-supported apron is proposed to prevent further erosion at Dam No. 12.

Mr. Saville.

Caleb Mills Saville,* M. Am. Soc. C. E. (by letter).—The hydraulic principles involved in the phenomenon of the "Hydraulic Jump" are treated in a very able and thorough manner by the author, and his paper is a most valuable and timely contribution, as so much engineering attention is being focused on "safety first" in the design of dams and appurtenant works. So clear has been the author's mathematical presentation of this subject that the most that remains is to bring forward examples of the nature of the hydraulic jump in special cases, and descriptions of the methods adopted to avoid danger in connection with this phenomenon.

In his work on the additional water supply for the City of Hartford, Conn., the writer has recently had under his direction both the design and construction of several dams, which are of considerable magnitude and importance on account of local conditions. In connection with these, it is proposed to present some features of design and observation.

* Hartford, Conn.

Mr. Saville.

The Nepaug Dam is a cyclopean masonry structure, arched in plan, and closing a narrow valley. It has both overflow and non-overflow portions, the drop from maximum reservoir level to slack water below the dam being about 107 ft. Fig. 32 shows a maximum section of the overflow portion. This portion is about 180 ft. long, and par-

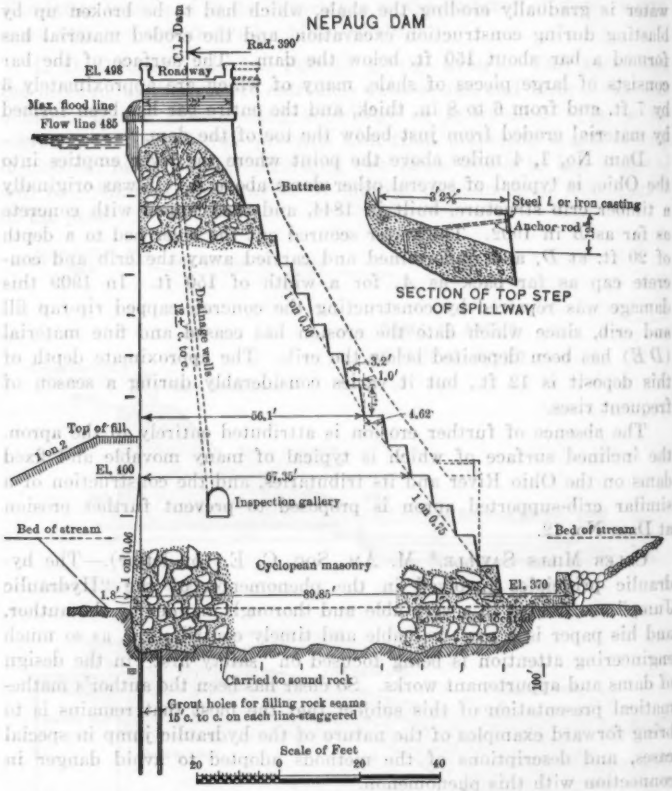

FIG. 32.

ticular attention was given to methods of breaking up the velocity which the water would acquire in falling over the dam and thus prevent it from doing damage at the down-stream base of the structure.

Two methods were used, both of which are indicated on the section. It is designed to break the smooth sheet of water passing over the ogee

crest by forcing it to jump from step to step down the incline, instead of allowing it to glide smoothly to the bottom under full momentum. As an additional help, the first step, just below the crest portion, is to be alternately depressed and raised in sections about 5 ft. long. As a second line of defence, the discharged water will be received in a pool

Mr. Saville.

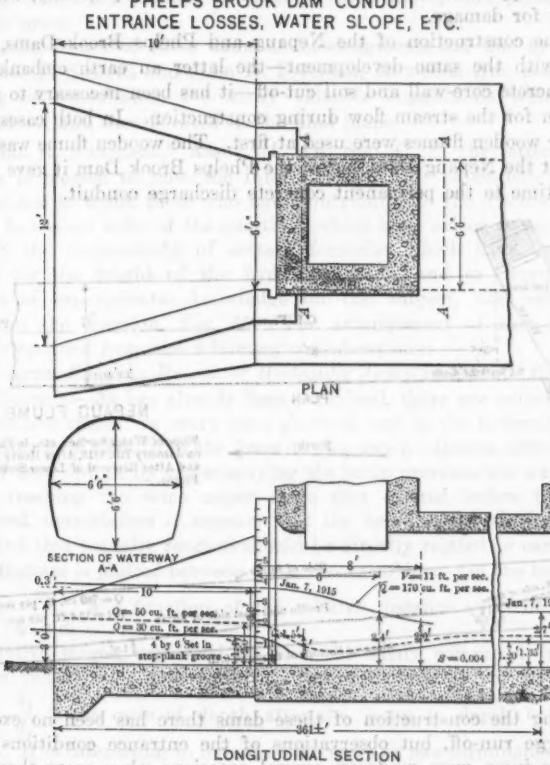

FIG. 33.

of dead water at the foot of the dam. The pool will be about 15 ft. deep, and will have a very massive concrete bottom with a baffle wall down stream. Both of these will be very heavily reinforced with steel, and the latter will be backed with large boulders. This provision is made in order to resist the force of the falling water and also the blow of any solid body that might come over the spillway. It is the expec-

Mr. Saville.

tation that the momentum of the water flowing over the spillway, on reaching the bottom, will be checked in the pool of dead water. Any energy that remains, however, will be expended, when the water is deflected back on itself by the obstruction of the baffle wall. During periods of considerable flow, the pool is expected to present a very turbulent appearance, but the water should flow away quietly, with no capacity for damage.

In the construction of the Nepaug and Phelps Brook Dams, connected with the same development—the latter an earth embankment with concrete core-wall and soil cut-off—it has been necessary to make provision for the stream flow during construction. In both cases, rectangular wooden flumes were used at first. The wooden flume was continued at the Nepaug Dam, but at the Phelps Brook Dam it gave place after a time to the permanent concrete discharge conduit.

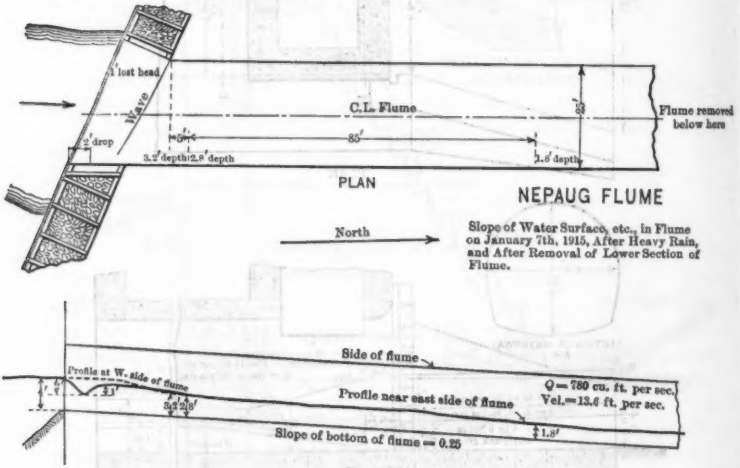

FIG. 34.

During the construction of these dams there has been no exceedingly large run-off, but observations of the entrance conditions and hydraulic jump were made on several occasions when more than the ordinary quantity of water was flowing. The conditions which obtained are shown by Figs. 33 and 34. On Fig. 33 it is interesting to note the effect on the low flows caused by the slight projection of the stop-plank. Fig. 34 shows that the construction conditions at the inlet have a very marked effect on the character of the flow at the entrance.

In the case of a third structure—Richards Corner Dam—across a stream draining 62 sq. miles of territory having very quick run-off

characteristics, a concrete conduit, having an inside width of 21 ft., and founded on ledge, has been designed to divert the water during construction. Having in mind flood conditions, when there might be some difference in head between the surface of the water in the pond and that flowing in the conduit, the apron at the approach was arched and thickened considerably in order to resist the upward pressure due to this cause. Mr. Saville.

In the design of these dams acknowledgments are due to Messrs. Frederic P. Stearns and John R. Freeman, Members, Am. Soc. C. E., acting as consultants, for many valuable suggestions which were worked out and incorporated in the final plans.

KARL R. KENNISON,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer is pleased to note the interest which this paper has aroused, and wishes to thank those who have contributed to the discussion. In order to answer some of the questions which have arisen to show more clearly the applicability of certain formulas which have been proposed for the height of the hydraulic jump, and to illustrate the extent of experimental knowledge on the subject, the writer has prepared the diagram, Fig. 35. The arrangement of this diagram was determined from the following considerations: Mr. Kennison.

Diagram Showing Height of Hydraulic Jump in Smooth Rectangular Channels.—As has already been explained, there are evidently two "alternative stages" in every open channel, and in the hydraulic jump the water level rises from the lower to the upper. Hence, although the loss of head ordinarily accompanying the jump prevents the water level from reaching the same upper stage that existed before the jump occurred, nevertheless it appears that the height theoretically attainable and that actually reached should be directly related to each other. The diagram is plotted between these two variables: On the horizontal scale, $\frac{v_1}{\sqrt{g\,d_1}}$ is a function of the relative distance apart of the two alternative stages, expressed so as to be easily computed from the known velocity, v_1, and depth, d_1, before the jump; on the vertical scale, $\frac{d_2}{d_1}$ is the ratio of depth after the jump to depth before the jump. It is interesting to note that the more or less formidable looking formulas to be found in the discussions of this paper can, without exception, be expressed with comparative simplicity in terms of these variables, and are easily plotted on this diagram.

Let the "alternative stage ratio", $\frac{v_1}{\sqrt{g\,d_1}}$, be represented by S, and the "hydraulic jump ratio", $\frac{d_2}{d_1}$, by J. Then the formula representing

* Providence, R. I.

Mr. Kennison.

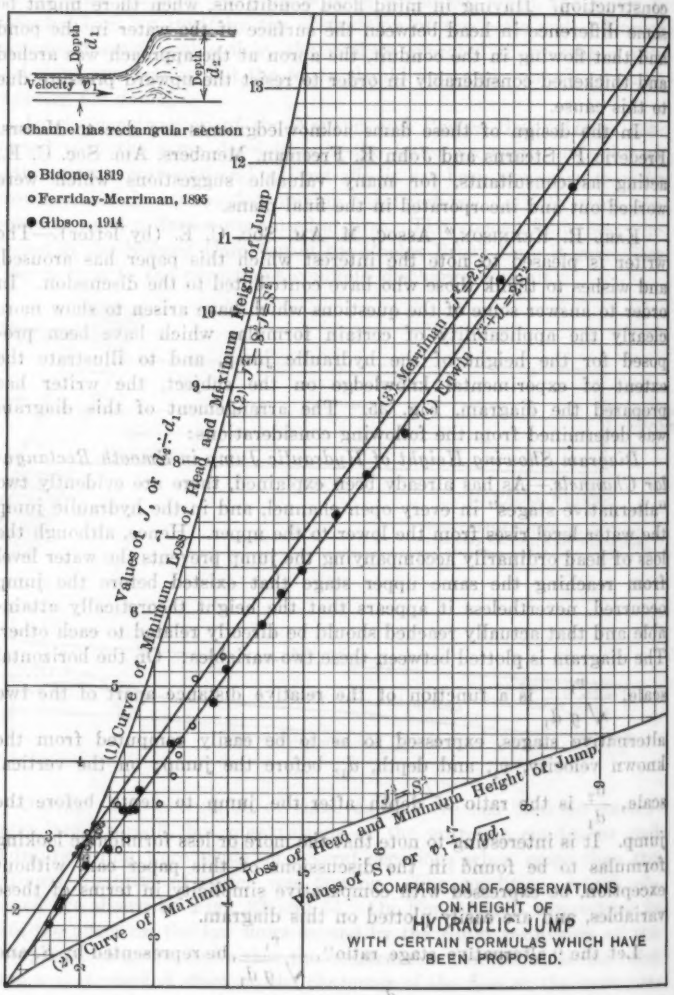

FIG. 35.

a jump to the theoretic upper alternative stage, without any loss of head whatever, is Mr. Kennison.

$$2J^2 - S^2 J = S^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

This formula, in its more complex form, was worked out in detail by Mr. Groat, on page 359, and by Mr. Johnson, on page 379. It is also identical with Professor Engel's formula, described by Mr. Andrews on page 374. In Fig. 35, this curve is labeled "Minimum Loss of Head and Maximum Height of Jump."

In direct contrast to this, the formula representing the jump to the "critical stage of maximum discharge under a given head" is

$$J^3 = S^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

In the diagram, this curve is labeled "Maximum Loss of Head and Minimum Height of Jump". Now, the only part of the diagram with which we are concerned is that lying between these two curves, as it is impossible for the jump to be higher than shown by Curve (1)* or lower than shown by Curve (2).

In Table 6 have been summarized some of the observations on the height of the hydraulic jump which have been called to the writer's attention. These have been plotted on Fig. 35. In general, these points appear to fall on a straight line drawn from the intersection of Curves (1) and (2). The vertical distance below Curve (1) corresponds to the loss of head occurring in the jump. Note that for small values of $\frac{v_1}{\sqrt{g\,d_1}}$, that is, when the two alternative stages are not far apart, the loss of head in the jump is relatively very small, as would naturally be expected. Practically all the earlier experiments, such as those of Bidone, were of this nature, and gave but little evidence as to what would happen with large values of $\frac{v_1}{\sqrt{g\,d_1}}$, as in the case of a spillway discharge. Mr. Robert Ferriday's experiments, the results of which Mr. Merriman has kindly put on record in his discussion of this paper, reached a value of 3.9 for $\frac{v_1}{\sqrt{g\,d_1}}$. Fig. 35 shows that the plotting of these results is not very uniform. One point falls quite a distance outside of Curve (1), an impossible result, which was noted also by Mr. Merriman.

The most remarkable tests are those by Professor Arnold H. Gibson referred to by Mr. Walker on page 388. One of the experiments was for a value of $\frac{v_1}{\sqrt{g\,d_1}}$ as high as 8.6. All these points come

* The actual jump could be very slightly higher since, due to our convenient erroneous assumption of uniform distribution of velocity throughout the section, the actual total energy head in the stream is slightly greater than computed.

Mr. Kennison.

remarkably close to a single line, apparently straight, and falling rapidly away from Curve (1); that is, the loss of head in the jump increases rapidly as $\frac{v_1}{\sqrt{g\,d_1}}$ increases, or as the alternative stages draw apart from each other. Some idea of what these values of $\frac{v_1}{\sqrt{g\,d_1}}$ mean is obtained by noting that, for a flood of 5 ft. over a 20-ft. dam, $\frac{v_1}{\sqrt{g\,d_1}}$ = about 7; over a 25-ft. dam, about 8; and over a 30-ft. dam, about 9. Attention is called, later, to an observation by Mr. Ewald on $\frac{v_1}{\sqrt{g\,d_1}} = 12.5$.

TABLE 6.—RATIOS, S AND J,

COMPUTED FROM OBSERVATIONS ON HYDRAULIC JUMPS.

* *Minutes of Proceedings*, Inst. C. E., Vol. CXCVII, p. 233. "The Formation of Standing Waves in an Open Stream," by Professor Arnold H. Gibson.

The diagram clearly shows the need of additional experiments with high values of $\frac{v_1}{\sqrt{g\,d_1}}$, and under a variety of conditions. The writer maintains that Professor Gibson's results, although very uniform among themselves, do not furnish sufficient evidence that the relative height of the jump will be the same under other conditions. In his experiments, which were carried on in a flume 3 ft. wide, observations were taken on the height of the tail-water necessary to bring the jump back close to a rectangular opening through which the water was being discharged along the bottom of the flume. Hence the discharge was the very steady discharge of an orifice, and not the free flow of an open channel such as Ferriday's. This may account for the remarkable uniformity of the observations.

Application of Hydraulic Jump Formulas.—In regard to the use of certain hydraulic jump formulas in the design of important structures for controlling the flow of water, Fig. 35

Mr. Kennison.

shows that the actual experiments which check these formulas are, for the most part, on small values of $\frac{v_1}{\sqrt{g\,d_1}}$, that is, under different conditions than obtain, for example, in the case of a high spillway dam. Mr. Merriman's formula, described in detail by Mr. Andrews on page 374, reduces to

$$J^2 = 2S^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and Professor Unwin's formula, described in detail by Mr. Andrews on page 376, reduces to

$$J^2 + J = 2S^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Fig. 35 shows that the Merriman formula gives values of $\frac{d_2}{d_1}$ greater than the Unwin formula by a nearly constant quantity, about 0.5. The Merriman curve crosses Curve (1) at the point, $\frac{v_1}{\sqrt{g\,d_1}} = 2.12$; hence, for values of $\frac{v_1}{\sqrt{g\,d_1}}$ less than about 2, it will give impossibly large values of the depth, d_2; and for values of $\frac{v_1}{\sqrt{g\,d_1}}$ equal to or a little greater than this, it should give correct results, especially if the jump occurs smoothly, with very little loss of head. Note the remarkable agreement between the Merriman formula and the Bidone experiments, in all of which the value of $\frac{v_1}{\sqrt{g\,d_1}}$ was nearly constant, from 2.0 to 2.3. The Unwin formula shows a remarkable agreement with the observations of Professor Gibson. Attention has been called in the paper and the discussions to the deduction of these formulas. It is hardly necessary to discuss them further. Note that the Unwin formula, which in its deduction does not define the loss of head in the jump, gives a height of jump less than the Merriman formula, which assumes a definite loss by "sudden expansion".

Regardless of the correctness or incorrectness* of the deduction of these formulas, Fig. 35 shows that, except for the less important lower values of $\frac{v_1}{\sqrt{g\,d_1}}$, they both give results which are remarkably close to the truth, judging from the scanty information at present available. Hence, if it were a question of predicting, as closely as

* The writer wishes to emphasize the statement that there can be no doubt that the original Merriman equation is in error. Mr. Andrews, in defending it, loses sight of the fact that Bernoulli's equation takes into account the retardation in velocity due to a rise in water surface.

possible, the height of jump in a given case, the writer would not hesitate to use these formulas, with modifications to fit the variation of the actual channel from the condition of a smooth rectangular flume. However, is it not more often a question of what is the least depth which must be maintained below the discharge, in order that there may be no doubt as to the occurrence of the jump? For such a purpose, and until more observations are available to check Professor Gibson's results, the writer would use greater depths than indicated by the formulas in question. If these depths are not attainable, are not such devices as the inexpensive Bassano Dam baffle piers, or Mr. Stearns' baffle wall, proper and reasonable means for taking the occurrence of the hydraulic jump out of the realm of uncertainty? Mr. Kennison.

Alternative Stages and Alternative Slopes.—Some questions have arisen in the discussion regarding the alternative stages described in the paper. It appears that at any point, in an open channel which is carrying a certain quantity of water under a certain head, there are two and only two surface levels or alternative stages at which the water can flow steadily. This conclusion has been checked by the thorough mathematical analysis of Mr. Groat. A vertical line drawn through his diagram, Fig. 14, shows at a glance the relative position of these two stages in channels of rectangular, and also parabolic, cross-section. Although, at any particular section, the position of the alternative stages is not dependent on channel slope, neither stage can be maintained indefinitely without the proper slope of channel bed, the lower high-velocity stage naturally requiring a steeper slope than the upper low-velocity stage. Mr. Johnson has discussed at some length the relation between these slopes, very appropriately called "alternative slopes". Take, for example, the case of a stream flowing swiftly at the lower stage over a channel bed of insufficient slope. The head is gradually used up by the friction under this high velocity. As the head decreases, the two alternative stages approach each other to within striking distance, when the surface jumps to the upper stage, which the channel slope is steep enough to maintain. Such a jump, formed on a line, V-shaped in plan, due mainly to the greater depth in the center of the stream, is not an uncommon sight.

Mr. Dunham has asked, since a negative root of an equation often has an unexpected and important meaning, what is the meaning of the root — 1.82 ft. which was discarded on page 344 leaving only two depths, 9.58 ft. and 2.24 ft., corresponding to the two alternative stages. The negative root, in this case, refers merely to the lower alternative stage at a point where the channel has been depressed a distance equal to twice the depth represented by the negative root.

Mr. Kennison.

For example, Figs. 4 to 9 show the two alternative stages, 9.58 ft. deep and 2.24 ft. deep, respectively, in the case of 50 cu. ft. per sec. flowing under a total head of 10 ft. Now, referring to Fig. 5, if Pond No. 2 is removed entirely, so that the water surface drops along the dotted line, as soon as a point is reached where the channel bed is 3.64 ft. below its original level, we have depth = 1.82 ft., velocity = $\sqrt{2g \times 11.82} = 27.5$ ft. per sec.; and, because the surface of the water is — 1.82 ft. above the original channel bed, this condition happens to satisfy the cubic equation.

Loss of Head in the Jump.—Both Mr. Merriman and Mr. Ewald have had exceptional opportunities for studying the hydraulic jump. They have suggested that there are possibly two types of jumps, the "true hydraulic jump" having a smooth surface throughout, instead of the turbulent profile shown in Fig. 11. From a study of Fig. 35, this contention seems plausible. For small values of $\frac{v_1}{\sqrt{g d_1}}$, that is, when the alternative stages are close together, the observations follow very close to Curve (1); the Bidone experiments, in particular, show very little loss of head, and such jumps as these must have occurred very smoothly. Mr. Ferriday's observation—that balls of putty, carried along the bottom of the flume, stopped dead just below the toe of the jump—appears to indicate that an eddy is formed in the bottom of the channel. In such cases as Mr. Merriman's "true hydraulic jump" it is possible that the main body of water flows up over this eddy to the upper stage very smoothly, with practically no disturbance or loss of head, except that in the eddy itself. If this is true, the effect of this eddy would be similar to that of a smooth concrete weir built up from the channel bed, which may explain Mr. Ewald's reference to the jump "forming within itself the controlling section". Referring again to Fig. 35: for all velocities higher than those corresponding to the Bidone observations the water is apparently unable to maintain this smooth rise, for there is a marked falling away from Curve (1). It appears that, although there may be a difference in the appearance of two jumps under the different conditions cited, nevertheless they are fundamentally the same phenomenon, namely, the passage from the lower to the upper alternative stage. In stating that the loss of head is not an inherent part of this phenomenon, the writer had reference to the same fact that was noted by Messrs. Merriman and Ewald, namely, that in some cases the loss of head is not in evidence, although in others it is large and unavoidable. Mr. Ewald's observation of the apparent adjustment of forces in certain jumps and the steady destruction of energy with a minimum of noise, reminding him of a smoothly

running motor under full load, is particularly interesting. Additional observations may possibly show a decided drop or break in the curve of Fig. 35 when $\frac{v_1}{\sqrt{g\,d_1}}$ reaches a value of about 2.5; otherwise the conclusion would be that there is no marked difference in type between those jumps that destroy much energy and those that destroy but little. Mr. Kennison.

Mr. Ewald has developed a formula for the hydraulic jump based on an assumption of loss by "sudden expansion" from the point, d_1, to the point, d_y, in Fig. 29, and but little loss after the point, d_y, is reached. It appears that he bases this diagram and the conclusions therefrom on the suggestions of the writer in the paper. If so, these suggestions were misunderstood. The water is flowing at the lower stage at d_1 and at the upper stage at d_2; but, at intermediate points, such as d_y, the conditions of internal pressure are so disturbed that the writer would not attempt to apply the laws of open-channel flow. If Mr. Ewald had in mind a controlling section formed within the jump itself, such as referred to above, then d_y should have been measured, not from the channel bed, but from the top of this controlling section, and the depth and velocity at such a theoretic controlling section, where depth $= \frac{2}{3}$ head, would be a function solely of the quantity discharged per foot of width, and not of the depth, d_2. It seems doubtful if such a controlling section within the jump itself can be formed, except with low values of $\frac{v_1}{\sqrt{g\,d_1}}$.

Mr. Ewald quotes an interesting experiment on a model dam. The observations, reduced so as to be plotted on Fig. 35, are $\frac{d_2}{d_1} = 14.3$, and $\frac{v_1}{\sqrt{g\,d_1}} = 12.5$. Unfortunately, this point falls outside the limits of the diagram as it was originally prepared. It falls about 15% below the Unwin curve, possibly due to the fact that actual channel conditions as represented in the model caused the jump to occur at a lower depth of tail-water than would be the case in a smooth rectangular flume. It is hoped that additional observations will take note of the effect of rough channels, elevated buckets, baffle piers, etc., in reducing the height of tail-water necessary to insure a flow at the upper alternative stage.

Since his first discussion of this paper, Mr. Johnson has submitted a very interesting discussion* of the theoretical losses involved in the hydraulic jump, concluding that the Unwin formula will give the correct height of jump in smooth rectangular channels. Mr. Johnson

* Page 380.

Mr. Kennison.

has apparently shown—what had not yet been made clear—that the Unwin formula, which was developed merely by considering the momenta before and after the jump, is thoroughly consistent in its derivation with an energy equation between velocity and pressure heads before and after the jump. He has shown that the Unwin formula contains in reality allowance for a definite loss of head, equivalent, say, to the total foot-pounds per second necessary to stop the backward flow, *B*, in an eddy such as shown in Fig. 36, plus an equal amount of power necessary to carry this flow ahead again, *C*, this eddy or eddies operating under a head equal to the rise in surface in the jump, and the quantity flowing in the eddies being such that the proper relation between static head and momentum is maintained, not only at the beginning and end of the jump, as in the Unwin formula, but throughout the jump, on the basis of static pressure being proportional to the depth. The writer does not assent to this last assumption, as one would expect the conditions of internal pressure to be more or less disturbed within the jump itself. Nevertheless, the remarkable agreement of the Unwin formula with actual observations is clearly shown by Fig. 35.

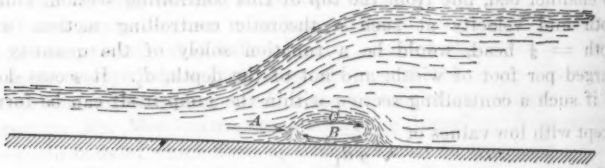

FIG. 36.

Mr. Johnson has not confined his losses to a single distinct eddy as shown at *B*, *C*, this Fig. 36 being more or less diagrammatic, to assist in discussing Mr. Johnson's theory. It also illustrates the foregoing reference to the jump forming within itself the controlling section, although, under high velocities, the loss probably occurs in many small eddies. Note that Mr. Ewald states: Pitot tube tests show that the quantity of water undergoing actual movement up stream is relatively small. Details of such tests are not given.

The total horizontal force, *A*, expended on the eddies is essential to the jump, as Mr. Johnson states, and is a measure of the loss of head in the jump; and, if this eddy was replaced by a smooth weir, no loss of head would occur, because, as Mr. Johnson clearly shows, the fastening of the weir to the channel bed keeps it from sliding up stream and obviates the necessity of the force, *A*.

Although the losses in the hydraulic jump under high velocities can be studied satisfactorily only by experimental observation, a reasonably correct theory as the basis for such studies is of great value.

Mr. Johnson's theory seems to be sounder than the few others which have been proposed, and is in excellent agreement with the actual observations now available. Mr. Kennison.

The Hydraulic Jump in Dam Design.—On account of the practical importance of the hydraulic jump in the design of spillway dams, this phase of the matter has received considerable attention in the discussions. The writer is indebted to Messrs. F. P. Stearns, C. M. Saville, L. D. Cornish, H. B. Muckleston, and E. W. Bush for the information which they have given, based on knowledge of actual conditions at important structures. Among other things, Mr. Stearns has called attention to a condition which is often overlooked, namely, the tendency of a concrete apron, from which the tail-water has been pushed down stream, to be forced upward by the excess pressure beneath it. Certain designs with which the writer has been connected have contained vent holes up through the concrete and inclined down stream, so that a slight suction would be produced to relieve the upward pressure under it.

The writer has already called attention in the paper to the destructive force of a spillway discharge. At seams in the rock foundation, the high velocity of the water is converted into pressure capable of tearing loose large masses of rock. It appears that this "Pitot tube action" is especially likely to erode rock which lies in horizontal strata. Mr. Cornish has given an excellent illustration of this in Fig. 31, and the erosion shown cannot be ascribed to the shape of the dam section. The writer has known of a similar case where horizontally stratified limestone was torn up, leaving a hole very similar to that shown below Dam No. 12 in Fig. 31. One piece of this limestone which was washed down stream weighed more than 20 tons. The erosion occurred close up to the toe of the dam, although the bucket was curved so as to deflect the discharge to an approximately horizontal direction.

The section of the Nepaug Dam shown in Fig. 32 involves noteworthy features, and the effect of the stepped face in preventing erosion of the boulder stream bed will be awaited with interest.

One important reason for knowing whether or not the flood height of tail-water is more than sufficient to cause the hydraulic jump, is this: If it is amply sufficient, then the back pressure of tail-water against the down-stream face of the dam may be counted on in computing the stability of the structure. If it is not sufficient, then none of this pressure above the bucket can be counted on, the only back pressure on the dam being the weight of the sheet of water and the reaction due to its deflection into a horizontal direction as it leaves the toe.

Mr. Kennison.

The hydraulic jump is indirectly connected with many other features in the design of works for controlling the flow of water, but the writer will not venture farther from the announced purpose of the paper, which was mainly "to call attention to the existence of the two 'alternative stages' in open-channel flow, and * * * to identify the 'hydraulic jump' as the passage from the lower to the upper stage."

In conclusion, the writer again thanks those who have contributed to the discussion, and hopes that additional observations will throw more light on the nature and extent of the energy losses occurring in the hydraulic jump.

Paper No. 1356

THE ACTION OF WATER UNDER DAMS*

By J. B. T. Colman, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. H. B. Muckleston, Warren B. Travell, Malcolm Elliott, James B. Hays, W. P. Creager, Edward Wegmann, W. R. Baldwin-Wiseman, John C. Oakes, H. W. King, Robert E. Horton, and J. B. T. Colman.

Synopsis.

This paper represents the results of a study of the action of water under dams, and was undertaken by the writer in connection with his graduate work at the University of Michigan. The attempt is made to investigate the relation existing between the height of water on the face of a dam, the length of the base of a dam measured perpendicular to the face, the distribution and upward pressure on the base of the structure, and the effect of sheet-piling placed at the heel and at the toe of the dam.

In procuring complete data for the determination of the foregoing factors, a second field was entered: that of the relation existing between the elements just mentioned, the porosity and effective size of the sand grains, and the resulting movement of the water through the porous medium.

The conclusions resulting from this investigation are stated at the end of the paper. A few of the more important ones are as follows:

The loss of pressure head of water in passing from above to below a dam may be divided into three stages:

* Presented at the meeting of September 5th, 1915.

(*a*) A relatively large loss of head, occurring where the water enters the sand;

(*b*) A quite uniform and comparatively small loss of head per foot of length through the body of the sand;

(*c*) A larger loss of head, occurring where the water leaves the sand.

The first stage or entrance loss is increased as the length of floor is decreased.

The rate of flow decreases very rapidly with the depth below the floor of the structure, being more concentrated for shorter floors.

The flow lines, once established in a porous medium, tend to continue horizontally as such, and come to the surface only after traveling a relatively great distance.

The porosity, effective size, and uniformity coefficient have little influence on the upward pressure exerted against the floor of a dam.

Piling at the heel of a dam reduces the pressure on the floor, and piling at the toe increases it.

Piling at the heel of a dam, to be effective, must be tight, very small leakage destroying its action.

Piling at the toe of a dam should be loose, in order to prevent increasing the upward pressure on the floor of the structure.

An impervious cut-off wall of comparatively shallow depth, say 5 ft., at the heel of the structure will greatly increase its stability by reducing the upward pressure on the floor.

NOMENCLATURE.

The following notation is used in the paper:

Numbers 1 to 46, inclusive, indicate different piezometer tubes.

a, *b*, *c*, and *d* are constants.

d represents the depth of sand in the box, in feet.

H represents the head of water against the face of the dam, in feet.

h_1 represents the height of the box above the sand surface, in feet.

h_2 represents the height of the tail-water above datum, in feet.

k is a constant.

l represents the floor length, measured on an element perpendicular to the face of the structure, and is given in feet.

M represents the moment about the heel of the dam, in foot-pounds.

o_1 represents the depth of opening below the sheet-piling at the heel, and equals $d - p_1$.

P represents the total upward pressure on 1 lin. ft. of floor, in pounds. P is used for the condition of no sheet-piling and P' for the condition of sheet-piling at the heel only.

p_1 represents the depth of sheet-piling at the heel of the structure, in feet.

p_2 represents the depth of sheet-piling at the toe of the structure, in feet.

S represents the hydraulic slope, and is equal to $\frac{H}{L}$.

x is a horizontal distance.

62.5 is the weight of 1 cu. ft. of water, in pounds.

Apparatus.

The tank or box, Fig. 1, was constructed of 2 by 12-in. by 16-ft. yellow pine, grooved on both edges for the insertion of tongues. Its inside dimensions were 15 ft. 2 in. long, 3 ft. 11¼ in. wide, and 5 ft. 6 in. high, in the lower or base portion of the dam, and 10 ft. high in the upper end, which was closed off by a bulkhead to form the height or face of the dam. The whole was held together by 4 by 6-in. yellow pine verticals, about 2 ft. from center to center, and bolted with ½-in. rods at the ends and ¾-in. rods at the centers.

Through the right side of the box and the floor of the dam extended forty-six ½-in. pipes, each of which led from a vertical plane at the center of the box through an elbow to a vertical glass tube. The tubes were adjusted to the desired height, and were connected to the pipe by rubber stoppers. The box, to a depth of 5 ft., was filled with sand which was settled by thorough wetting. On top of the sand was placed a floor, 8 ft. 3 in. long, the front or heel end of which was 4 ft. from the end of the box. On this end was placed the bulkhead, which, with the floor, formed the dam. All corners and the two sides of the floor were made water-tight by caulking the joints with oakum. The desired weight on the floor of the dam was obtained by two 18-in., 3-ton, screw jacks acting between blocking placed on the floor and the reinforced concrete ceiling.

The required head above the dam was obtained by leading water from the tap through a ½-in. hose to the chamber formed by the bulkhead. Any desired head up to 5 ft. 2 in. could be obtained by adjusting the tap. To provide for conducting waste-water from the toe of the dam, a 1¼-in. pipe was led through the side of the box to a drain. That the tail-water might be kept at a constant elevation, it was necessary to provide a means of breaking the siphon action in the pipe. This was accomplished by placing a box with a closed bottom and open top over the end of the pipe, the top of which was cut off about ⅛ in. below the desired water elevation. To aid further in regulation, several small holes were bored through the sides of the box. These were closed at times of small discharge, and the proper number opened to keep the water spilling over the top, at a uniform depth.

To assist in making observations, a straight-edge was adjusted by a level to the elevation of the tail-water surface and nailed rigidly to the 4 by 6-in. verticals of the box. This elevation was called zero. All readings are positive, and taken in feet and hundredths. Tube No. 1 gives the elevation of the free water surface. Tubes Nos. 2 to 45, inclusive, with the exception of Nos. 16, 22, 26, 30, 33, 36, and 41, pass at various points through the sides of the box, and give, in feet of water column, the equivalent pressure head in the sand at the ends of the pipes. Pipes Nos. 16, 22, 26, 30, 33, 36, 41, and 46 lead through the center of the floor and show the pressure heads against the floor of the dam directly.

Operation.

Observations were taken on two sands: *A* and *B*. The first was a natural sand, obtained from a local pit. It was of sizes varying from large pebbles to fine grains, and contained very little clay. Sand *B* was obtained by screening the first through a ½-in. square mesh screen, which removed about 35% of the larger pebbles. With Sand *A* in the box, three different sets of experiments were made: (1) with no piling at the heel or toe; (2) with water-tight piling extending to a depth of 2 ft. 7 in. at the heel; and (3) with the same piling at the heel and piling 2 ft. 3 in. deep at the toe. With Sand *B* seven sets of experiments were made: three with different lengths of floor, and four with the floor 8 ft. 3 in. long, and different depths of sheet-piling.

The three floor lengths were: 8 ft. 3 in., 6 ft. 3 in., and 4 ft. 3 in. The observations with the sheet-piling were, with piling 1, 2, and 3 ft. deep at the heel, and with piling 3 ft. deep at the heel and 18 in. deep at the toe.

A set of experiments is made up of two or more experiments, each of which comprises a number of different readings. After water was turned on, the time allowed for the head to adjust itself, before making a reading, was not less than 2 hours. This was done in order that the pressure head might be transmitted to all points in the tank and that the resulting tube readings would indicate the proper relation of one tube to the other.

The pressure on the floor of the dam was kept as nearly uniform as possible throughout the experiments. This was done by frequently adjusting the jacks to a definite pull of a spring balance on the end of a 1-ft. lever arm. To determine the proper pull, the jacks, with the balance, were first gauged or rated in one of the laboratory testing machines. This pressure, which amounted to 5 tons in all except the last two sets of experiments, was uniformly distributed over a floor area 3 ft. 11 in. wide and 8 ft. 0 in. long (3 in. of the floor under the bulkhead was not connected to the main floor except by caulking) and amounted to about 320 lb. per sq. ft. The loading was intended to approximate what might be expected from a vertical-faced, reinforced concrete structure of a similar height.

In the last two (or short floor length) experiments, the load was 3.75 tons for the 6-ft. length and 2.5 tons for the 4-ft. length, which, as before, gives an average pressure of 320 lb. per sq. ft. With the 4 ft. 3-in. floor length two additional observations were taken, one with the load increased to 5 tons, or 640 lb. per sq. ft., and one with a load of 1 ton, or about 125 lb. per sq. ft.

In order to determine the quantity of seepage, the discharge, for a time varying from 1 to 5 min., was turned into a tank which rested on a scale. This was weighed and recorded for each observation.

Data.

For convenience and simplicity all the data have been arranged in the form of tables and diagrams.* Tables 1 and 2 (Plates XIV and XV), are of similar form, the first being for Sand *A* and the

* All these diagrams have been filed in the Library of the Society for reference.

second for Sand *B*. The experiment and observation numbers have no special significance; they merely indicate the method of keeping the readings in order. In general, the experiment number refers to the day on which readings were taken, and the observation number refers to the different readings taken in a single day. The date and hour of making the observation are given, and also the temperature of the water, in degrees Fahrenheit, the approximate load on the floor, in tons, and the seepage through the sand beneath the dam, in cubic feet per minute. The remarks column indicates the arrangement of the box while making each set of experiments. The columns having the general heading, "Height of Water in Tube No. ——" give the individual readings of elevation of water in the glass tubes above tail-water, as previously described.

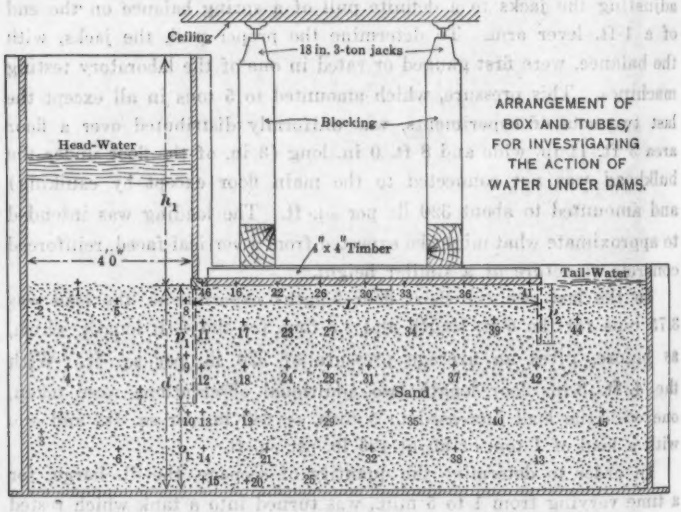

FIG. 1.

Table 3 with Fig. 1 forms a key to the succeeding curves, and sums up the ten sets of observation, as previously outlined, indicating the porosity, effective size, and uniformity coefficient of the sands, and the dimensions, as shown by the letters on Fig. 1. Fig. 1 is a section of the box on the center line, and shows the arrangement of the tubes and their numbers.

Sand Analysis.

That the data might not be limited in their use, but have a general application, the porosity and size of the sand grains of samples of each sand were carefully determined. Five samples of Sand *A* had porosities of 0.284, 0.294, 0.300, 0.289, and 0.284, respectively, the average being 29 per cent. Four samples of Sand *B* had porosities of 0.319, 0.319, 0.318, and 0.319, respectively, or an average porosity of approximately 32 per cent.

For determining the size of the sand grains, it was realized that the method must be reasonably accurate, easy of duplication, and preferably serviceable in the field. Accordingly, the sieve analysis method was adopted. This consists in using a series of sieves, putting a sample of known weight in the coarsest, shaking the sieves until no more sand would pass, and then weighing the portion of the sample passing each sieve.

The effective size (that is, a size such that 10% by weight is smaller and 90% is larger) of Sand *A* was found to be 0.04 in., and of Sand *B* 0.027 in. The uniformity coefficient, or the ratio of the 90% to the 10%, is 8 for Sand *A* and 5.4 for Sand *B*. The sieve size and weights passing each are shown in Table 4.

Plotting.

All readings were plotted in the form of equal-pressure curves. Briefly, this consists of preparing an outline of the box, with the location of the tubes indicated thereon by crosses and numbers. The scale adopted was 1 in. = 1 ft., both vertical and horizontal. Having prepared the outline, the pressure head, as read from the tubes, was marked on each, and the points of equal pressure were connected by contours. These curves at once give a picture of what takes place in the porous sand medium beneath the structure.

For the purpose of leveling the data, all observations were also plotted in the form of head, pressure-head curves. That is, the heads against the dam were plotted as ordinates and the pressure heads in the tubes as abscissas. Individual points were plotted for each tube reading, different marks being used for each arrangement of the box. All points were plotted before drawing any curves. A whole family of points, or set of experiments, was then studied, and the form of curve which would best fit all points was determined. The curves were then drawn so as to conform closely to the plotted points, and at the same time not diverge from the general family type. These curves served a double purpose, first to study the data and see how the pressure varied from point to point, and second to level the data, that is, to charge one error in observation against another and obtain the average or more probably correct reading.

A few representative equal-pressure curves for the different arrangements of the box with Sand *B*, are shown on Figs. 2 to 8. The *H*, with each equal-pressure diagram, refers to the head against the dam when the observation was made. The experiment number, observation number, and data refer to the data in Table 2 (Plate XV).

With readings taken from the leveling curves for the tubes numbered 46, 16, 22, 26, 30, 33, 36, and 41, ten series of pressure curves were constructed. These represented the amount and distribution of the upward pressure on the floor of the dam for each set of experiments. Each series of pressure curves was made up of five curves, one for each foot of head from 1 to 5 ft., inclusive. The scale used originally was 1 in. on the paper = 1 ft. of pressure head; so that if the total area below the pressure curve was found to be *A* square inches, the upward pressure, in pounds on a 1-ft. length of dam, would

be 62.5 $\times$ A. The seven floor-pressure curves for the various arrangements of the box with Sand B are shown in Figs. 9 to 15.

The next step was to measure, with a planimeter, the areas below each of the curves and determine the distance from the heel of the dam to the centroid or center of pressure for each area. These are arranged in convenient form in Table 5. Using the slopes (or the head divided by the floor length) as ordinates and the areas as abscissas, the areas were then plotted in ten slope-pressure curves, Figs. 16 and 17.

INVESTIGATORS.

Before proceeding to the discussion of the data, it might be interesting to review briefly the findings of the all too few investigators of this important subject—"The Action of Ground-Waters." In 1856, Henri Darcy,* stated that the velocity of flow of ground-water was proportional to the slope of the hydraulic gradient, and varied inversely as the length of the porous medium through which it acted. Isaac Roberts,† demonstrated that the flow of water through sandstone varies with the pressure. Seelheim,‡ of Wiesbaden, stated that the velocity of flow increases faster than the pressure producing it.

Allen Hazen, M. Am. Soc. C. E., states§ that the flow varies approximately as the square of the effective size of the sand grains. J. H. Fuertes, M. Am. Soc. C. E., also shows‖ that the velocity coefficient is materially affected by variation in the size of the sand grains. R. Cohen** proves that the viscosity of water varies inversely as the pressure. Several experimenters have shown that the viscosity of water increases with the temperature.

W. R. Baldwin-Wiseman,†† experimenting on the porosity of rock, shows that the flow increases faster than the pressure, also that the variation of pressure throughout a column is greatest near the surface, though the variation within the mass is more uniform and relatively small.

C. S. Schlichter* gives a mathematical proof and formula for the flow of ground-water, which is:

$$Q = 0.2012 \frac{p\, d^2\, s}{\mu\, h\, k},$$

in which Q is the number of cubic feet of water transmitted by a column of sand in 1 min.; p is the difference in pressure at the ends of the column under which the flow takes place, in feet; d is the effective size of the sand grains, in millimeters; μ is the number which takes account of the friction between the particles of water, or the coefficient of viscosity; and k is a constant which depends on the porosity of the sand.

Mr. Allen Hazen, who experimented with the vertical flow in sand filters, gives the following formula for the velocity of water through sand:

$$v = c\, d^2 \frac{h}{l} (0.70 + 0.03\, t),$$

in which v is the velocity of water, in meters, daily, in a solid column of the same area as that of the sand; c is a constant approximating 1 000; d is the effective size of the sand grains; h is the loss of head between the two ends of the sand column; l is the thickness through which the water passes; and t is the temperature, on the centigrade scale.

Other formulas might be given, but they would only be repetitions, and would not serve to clarify the subject. It is obvious that some of these equations are mathematical solutions of assumptions, and that others are derived from uniformly distributed vertical flow. The true laws of ground-water action can be shown only by experiment with horizontal flow; and, because of their complex nature and the variation of the factors, the work must be conducted on a large scale.

Discussion.

The principles governing the action of water under pressure in the sand forming the foundation of any structure, such as a weir or dam, may be compared with the action of water in a large number of small pipes. The upper ones would represent the sand layer adjacent to the weir floor, the second ones the next lower layer, and so on, until, in a sand of relatively great depth, the tubes representing the

* Nineteenth Annual Report, U. S. Geological Survey, Part II.

lower layers would have a length many times that of those in the first layer. These imaginary tubes extend from different points in the floor of the reservoir to points at various distances down stream from the toe of the weir.

Lines of Equal Pressure.

In taking up the discussion of the equal-pressure contours, dams without sheet-piling at the heel or toe will first be considered. All lines of equal pressure start from the lower surface of the floor of the dam and extend in directions, varying from nearly horizontal up stream to a similar position down stream from the structure. These lines naturally fall into three divisions: The first, or higher-pressure contours are relatively closer together, and, in carrying out the pipe analogy, would be comparable with entrance pressure. The difference in pressure between any two contours represents loss of head, and is comparable with entrance loss in pipes. The second division comprises the contours through the body of the sand. They are quite uniformly spaced, and are comparable with the loss of head in pipes due to friction. The third division is that of the lower-pressure contours, which are closer to one another and indicate a greater loss of head in the last portion. Thus it is seen that, in any element of water which passes from above the dam to a position below the structure, there is, through entrance eddies in the first division, a comparatively great loss of head. After this, the flow lines become nearly parallel, and head is expended at a uniform rate until near the vicinity of exit from the sand particles. Here eddies again break up the flow lines and tend to resist the exit of the water from the sand.

Lines drawn on each diagram perpendicular to the pressure contours would indicate the paths followed by the particles of water from point to point, and show the distribution of flow. These lines would be much closer to one another just below the floor of the dam than at greater depths. This indicates that the flow is greatest near the floor and decreases with the depth.

By comparing the pressure diagrams for different lengths of floor, it will be seen that the shorter floors give the greater entrance loss. It will also be noticed that the flow lines in the shorter floor diagrams are concentrated near the floor more than in the longer ones. In

FIG. 4.

this case there are but few lines, and a resulting small flow at greater depth.

Turning to the pressure diagrams of sheet-piling at the heel only, and comparing them with those of no piling, it will be observed that the higher-pressure contours extend from the piling forward in nearly horizontal lines, and that the succeeding contours are moved forward, showing reduced pressure throughout the foundations. The short contours, back of the piling and extending from the piling to the floor, indicate a region of very small movement of water.

The greater number of flow lines follow down the face of the piling to its lower end. Here they turn down stream and rise to the surface at some distance beyond the floor of the dam. At the end of the piling they spread out fan-like through nearly a quadrant, a few turning vertically upward back of the piling. By far the greater number, however, approximate the shortest path from the bottom of the piling to a point a short distance beyond the floor. The piling increases the length of the flow lines, but exposes a greater depth of soil to the attack of the water. This, in turn, necessitates a less degree of concentration beyond the piling, and offers less resistance to the movement of the water.

By comparing the diagrams of 1, 2, and 3-ft. piling (Figs. 5, 6, and 7), it will be observed that the 1-ft. piling increases the depth exposed to flow-line attack, decreases the distributed pressure throughout the foundation, and increases the length of flow line but little. With the 2 and 3-ft. piling, the area exposed to flow-line attack is increased, but in a relatively less degree, the area near the floor of the dam decreasing in effect with the increased depth of piling. Likewise, it will be observed that, with the greater depth of piling, there is less distributed pressure throughout the foundation and an increased length of flow line.

Turning to Experiments Nos. 12 to 16, inclusive (Fig. 8), it will be observed that the piling at the toe of the dam acts in the opposite manner to that at the heel. This decreases the area exposed to the flow-line attack, and increases the pressure throughout the foundation; but, acting in a way similar to the heel piling, it also increases the length of flow line.

To make the piling at the heel effective, it must be water-tight. It was found that a very small leakage through the piling destroyed

FIG. 7.

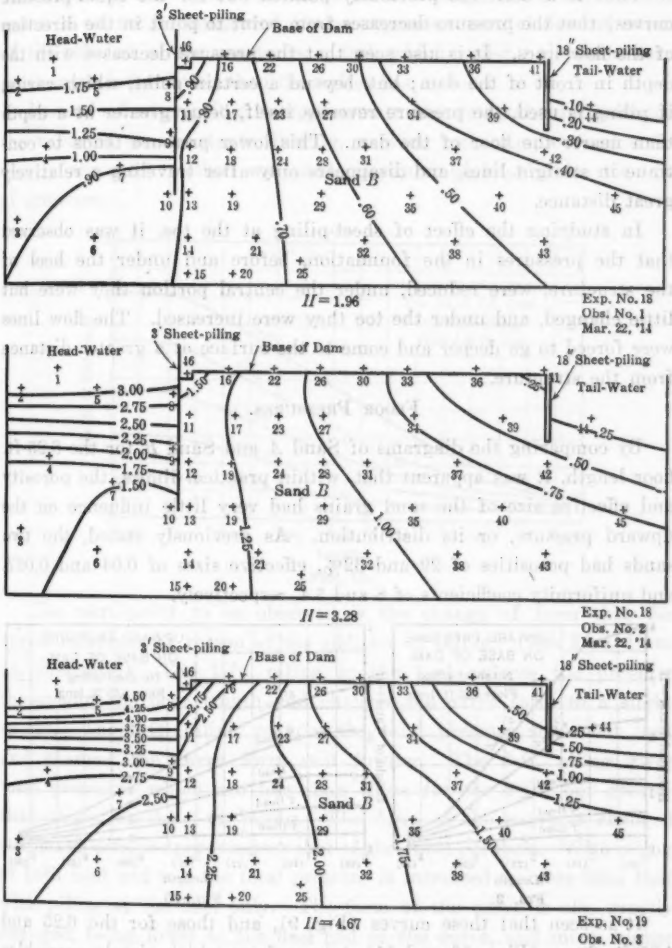
its effect. To eliminate the increased upward pressure, resulting from the toe piling where used, the latter should be loosely driven, in order that the flow may escape.

Pressure In Tubes.

The pressure head in a few of the typical or critical tubes will next be considered. Each of the leveling curves, as previously explained, represented a different arrangement of the box. Of these arrangements, there were seven for Sand *B*, and three for Sand *A*. The six curves for Sand *B*, with three different floor lengths and three different depths of piling at the heel, will be treated first. In Tubes Nos. 2 and 5 all curves for the 8.25-ft. floor fall very close to one another, showing that, at points a short distance in front of the dam, the piling had little or no effect on the pressure head. The curves which represented the shorter floor lengths showed less pressure head than those for the longer floor length, and indicated a greater concentration of flow lines at the heel of the dam.

Tubes Nos. 10, 13, 14, and 15 had curves which were very similar. They showed reduced pressure heads for the longer lengths of sheet-piling, and also, within the range of observation, showed decreased pressure heads for the shorter floor lengths. Tube No. 11 also showed decreased pressure for each increased length of piling and, for the shorter floor lengths, gave values which range between those of the 1 and 3-ft. piling with the greater floor lengths. The changes for the latter tube were relatively much larger than for the former ones. Tubes Nos. 25, 32, 35, and 40 had curves very similar to those for the previous tubes, the only difference being that of magnitude of pressures, which decreased from tube to tube in the direction paralleling the lines of flow.

In Tube No. 27 the pressure heads were considerably less than in those of Tube No. 11. However, the more noticeable change was that the curves, arranged in order of greatest pressure, were first those for no piling, then those for 2-ft. piling, and finally those for the 1 and 3-ft. piling, which were almost identical. This is explained by the action of the flow lines. The greater number for the 2-ft. piling passed close to Tube No. 27, whereas, for the 1 and 3-ft. piling, they passed above or below this point. It is also seen that, for the shorter floor lengths, the pressure was greatly reduced at this point.



LINES OF EQUAL PRESSURE, IN FEET OF WATER, UNDER MODEL DAMS.

Numbers represent piezometer tubes
See Table 2 for data

FIG. 8.

Thus it is seen (as previously pointed out for the equal-pressure curves) that the pressure decreases from point to point in the direction of the flow lines. It is also seen that the pressure decreases with the depth in front of the dam; but, beyond a certain point, which varies, if piling is used, the pressure reverses itself, being greater at a depth than nearer the floor of the dam. This lower pressure tends to continue in straight lines, and disappears only after traveling a relatively great distance.

In studying the effect of sheet-piling at the toe, it was observed that the pressures in the foundation, before and under the heel of the structure, were reduced, under the central portion they were but little changed, and under the toe they were increased. The flow lines were forced to go deeper and come to the surface at a greater distance from the structure.

Floor Pressures.

By comparing the diagrams of Sand *A* and Sand *B* for the 8.25-ft. floor length, it was apparent that, within practical limits, the porosity and effective size of the sand grains had very little influence on the upward pressure, or its distribution. As previously stated, the two sands had porosities of 29 and 32%, effective sizes of 0.04 and 0.027, and uniformity coefficients of 8 and 5.4, respectively.

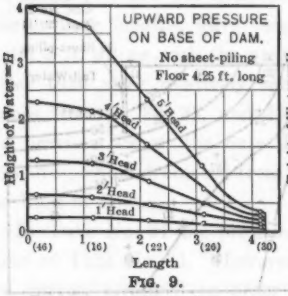


Fig. 9.

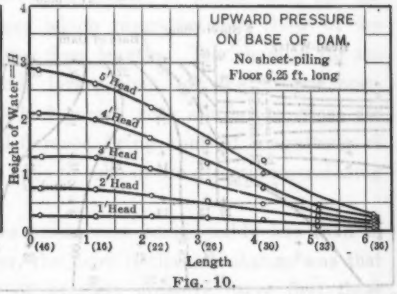

Fig. 10.

It is seen that these curves (Fig. 9), and those for the 6.25 and 4.25-ft. floors (Figs. 10 and 11), take a form which closely resembles the curve of the law of error. In fact, if P represents the pressure at any point, and x the distance from the heel to P, the law is very closely approximated by the equation:

$$P = a\,10^{-kx^n}$$

where a, — k, and n are functions of the floor length and head. As this equation cannot be integrated, its use requires a careful determination of the relation of the constants, a task which would necessitate very much more information than the writer has at hand.

Instead of attempting to approximate the integral, or determine the value of the constants directly, a much more simple (and sufficiently accurate) method was used, as explained later under the law of pressures.

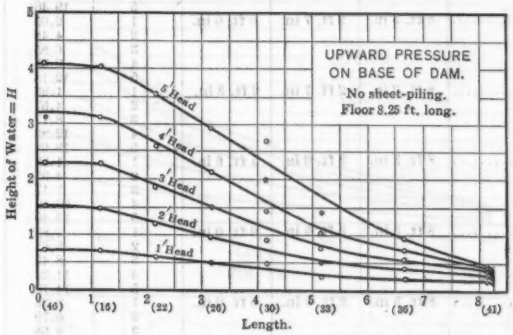

FIG. 11.

The next point to be observed is the change of form that the curve undergoes by reason of the addition of piling. (See Figs. 12 to 15, inclusive.) The 1-ft. piling at the heel reduces the pressure throughout the floor length and changes the curve form to a slight extent. The 2-ft. piling reduces the total pressure somewhat less, and changes the curve form still further. The 3-ft. piling gives total pressures which are less than those for the 2-ft., but greater than those for the 1-ft. piling. The form of the curve is changed still more until it approximates that of the cubic parabola. With piling at both heel and toe, the total pressure is increased to more than that with piling at the heel only. The form of the curve is also greatly changed, being lower at the heel end of the curve, and much higher at the toe end.

The areas of these pressure curves, and also the distances from the heel of the dam to the center of pressure are given in Table 5. By studying the values of the centroid distances, it will be seen that, for all floor lengths without piling, the center of pressure approximates

TABLE 5.—AREAS OF UPWARD-PRESSURE CURVES, AND DISTANCES OF THE CENTROIDS FROM THE HEEL OF THE DAM.

very closely to one-third of the floor length from the heel $\left(\frac{L}{3}\right)$. For piling at the heel, this value is decreased slightly for the 1-ft., and increased slightly for the 2 and 3-ft. piling; but the error introduced by using the arbitrary value, $\frac{L}{3}$, would be very small, and on the

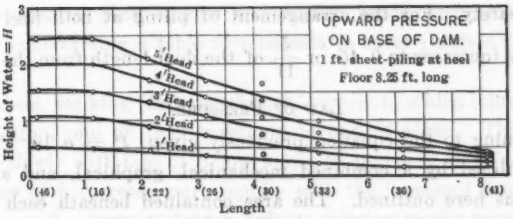

FIG. 12.

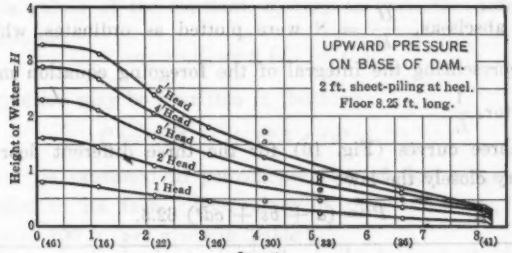

FIG. 13.

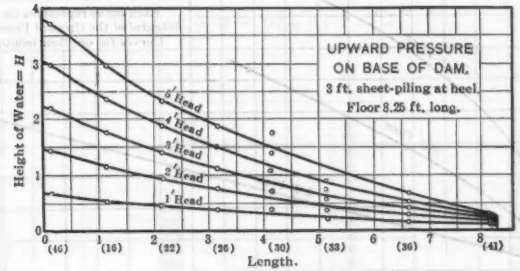

FIG. 14.

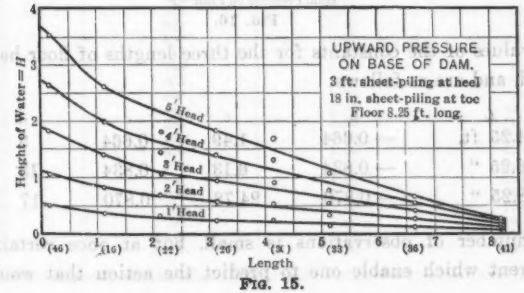

FIG. 15.

side of safety. For the arrangement of piling at both heel and toe, this value increases to 0.45, or $\frac{5}{11}$ of the floor length from the heel.

Law of Pressure.

Returning to the equation previously given, $P = a\ 10^{-kz^n}$. This was simplified by a combined mechanical, graphical, and analytical method, as here outlined. The area contained beneath each pressure curve was carefully measured with a planimeter. Then, on these areas as abscissas, $\frac{H}{L} = S$ were plotted as ordinates, which gave curves representing the integral of the foregoing equation multiplied by the factor, $\frac{1}{L}$.

The three curves (Fig. 16) for the three different floor lengths follow very closely the law:

$$P = (a + bs + cd^s)\ 62.5.$$

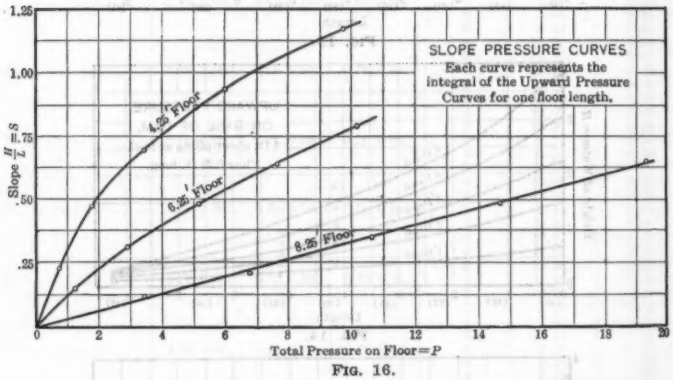

FIG. 16.

The values of the constants for the three lengths of floor have been computed, and are as follows:

L	a	b	c	d
4.25 ft.	— 0.664	1.49	0.664	9
6.25 "	— 0.834	6.13	0.834	13
8.25 "	— 0.870	24.78	0.870	17

The number of observations is small, but at once certain facts are apparent which enable one to predict the action that would take

place for greater floor lengths and higher heads, and provides the means of constructing a table of constants to cover possible cases that may arise.

The most striking fact is that $a = -c$, which changes the equation from one of four constants to one of three. Their value increases slowly with that of L, and seems to approach unity as a limit. The values of b increase more rapidly with the increased floor length, but, like a and c, seem to bear a definite relation to the length of the floor. The values of the constant, d, vary as twice the difference in floor length, or:

$$d_1 - d_0 = 2\ (L_1 - L_0).$$

This equation may be rewritten in the form:

$$P = 62.5\ bs + 62.5\ c\ (d^s - 1),$$

in which P is expressed in pounds per foot of dam measured on a line parallel to its face. The values of these constants, for floor lengths up to 100 ft., are given in Table 6.

TABLE 6.—CONSTANTS FOR THE FORMULA:

$$P = 62.5\ bs + 62.5\ c\ (d^s - 1).$$

L	b	c	d
4	1.3	0.60	8.5
6	5.1	0.82	12.5
8	24	0.86	16.5
10	48	0.88	20.5
12	80	0.90	24.5
14	120	0.91	28.5
16	165	0.92	32.5
18	222	0.93	36.5
20	278	0.94	40.5
22	234	0.95	44.5
24	393	0.96	48.5
26	450	0.96	52.5
28	508	0.97	56
30	565	0.97	60
32	623	0.97	64
34	680	0.97	68
36	737	0.98	72
38	795	0.98	76
40	853	0.98	80
45	997	0.99	90
50	1 142	0.99	100
55	1 286	0.99	110
60	1 431	0.99	120
65	1 576	1.00	130
70	1 720	1.00	140
75	1 865	1.00	150
80	2 009	1.00	160
85	2 154	1.00	170
90	2 298	1.00	180
95	2 443	1.00	190
100	2 587	1.00	200

In applying this law, it should be remembered that the center of pressure of the force, P, is $\frac{L}{3}$ from the heel of the dam, and if moments are taken about that point, M, in foot-pounds, is indicated by the expression:

$$M = \frac{P\,L}{3}.$$

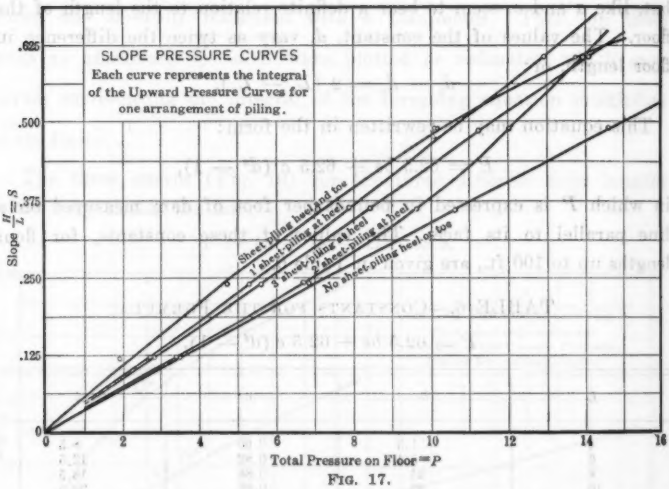

FIG. 17.

Taking up the curves (Fig. 17) for the sheet-piling at the heel, it is seen that these (unlike those for different floor lengths without sheet-piling, where P increased more rapidly than S) give results in which P increases less rapidly than S. The law governing this action and its association with the condition of no sheet-piling is not a simple relation. An approximate formula, which can be easily applied, is:

$$P' = P\,kp_1.$$

Now, if this equation is combined with the previous one for P, we have:

$$P' = [62.5\,bs + 62.5\,c\,(d^2 - 1)]\,kp_1.$$

The values of k are given in Table 7, from which it will be seen that the product, kp_1, changes but little with the change of slope for

values of p_1 greater than five; or, a 5-ft. depth of impervious cut-off wall is the practical limit in the reduction of the upward pressure on the floor of a dam.

TABLE 7.—VALUES OF THE CONSTANT, k, FOR THE FORMULA: $P' = [62.5\ bs + 62.5\ c\ (d^2 - 1)]\ k\ p_1$.

p_1	Slope 60 : 100	Slope 48 : 100	Slope 36 : 100	Slope 24 : 100	Slope 12 : 100
1	0.65	0.69	0.73	0.77	0.81
2	0.36	0.40	0.44	0.46	0.48
3	0.24	0.25	0.26	0.27	0.28
4	0.18	0.18	0.19	0.19	0.20
5	0.14	0.14	0.14	0.14	0.15

Taking up the condition of sheet-piling at both heel and toe, it is seen that P increases more rapidly than S. For low values of S, P is less than for the condition of no piling, but increases more rapidly as S increases, and crosses the first curve.

SEEPAGE.

With each pressure observation the temperature and discharge per minute were recorded. These discharges when corrected for temperature afford a partial means of comparing the effects on the quantity of seepage for different floor lengths and sheet-piling conditions, but are of no use in determining the law that governs the underflow. This law depends, not only on the length of the overlying impervious layer, the enforced length of flow, and the head of water, but on the porosity, the effective size of the sand grains, the uniformity coefficient, and the viscosity of the water. These factors are all very complicated, and at present are so little understood that an accurate formula is impossible.

The writer attempted to determine this law, in connection with his work, but was unsuccessful. The method used imitated that used by Schlichter for determining the velocity of underground water. Through the center of each of sixteen tubes scattered throughout the box a rubber insulated wire was passed, from the end of which the insulation for about 2 in. was cleaned. This bared wire, with the end of the pipe, formed two electrodes. The circuit was completed by connecting it with the lighting system, in one lead of which an ammeter was introduced.

The operation, as arranged and carried out, consisted of making readings of all tubes at 5-min. intervals. After two or three readings had been made, ordinary rock salt was introduced into the water above the dam. The 5-min. observations were continued until all traces of the salt had disappeared. These observations were then plotted, with times as abscissas and currents as ordinates, the peaks of the curves being taken to indicate the time required for the salt solution to reach the tube. The time required for the flow to pass from Tube a to Tube b would be $t_b - t_a$, and the velocity of flow over the distance, d, would be $\frac{t_b - t_a}{d}$.

In many of the readings this gave very high velocities under the toe of the dam, where the flow lines were well distributed; in fact, it frequently gave negative results, showing that the solution had passed by one tube and reached the second before influencing the reading of the first tube. After several attempts, these electrical observations, because of the unsatisfactory results and the undesirability of interfering with the pressure experiments, were discontinued.

However, the trials were sufficient to point out a more satisfactory method of attacking the problem. Each tube carrying an electrode should be arranged so that the salt solution could be charged at that point. Then, by charging one tube at a time and making readings as before, the time required for the flow to pass 1, 2, or 3 ft. could be determined. In arranging the tubes, care should be taken to make it unnecessary to trace any one charge for a greater distance than 3 ft.

Conclusions.

The conclusions resulting from this investigation may be stated as follows:

1.—The loss of pressure head of water in passing from above to below a dam may be divided into three stages:

(*a*) A relatively large loss of head, occurring where the water enters the sand;

(*b*) A quite uniform and comparatively small loss of head per foot of length through the body of the sand;

(*c*) A larger loss of head, occurring where the water leaves the sand.

2.—The first stage or entrance loss is increased as the length of floor is decreased.

3.—The rate of flow decreases very rapidly with depth below the floor of the structure, being more concentrated for shorter floors.

4.—The flow lines, once established in a porous medium, tend to continue horizontally as such, and come to the surface only after traveling a relatively great distance.

5.—The pressure decreases with the depth in front of the dam, and below the structure it reverses itself, increasing with the depth.

6.—The porosity, effective size, and uniformity coefficient have little influence on the upward pressure exerted against the floor of a dam.

7.—The pressure curve for the condition of no piling closely resembles the probability curve, having the general form

$$y = \frac{h}{\sqrt{\pi}} e^{-h^2 x^2}.$$

8.—Piling at the heel of a dam reduces the pressure on the floor, and piling at the toe increases it.

9.—With sheet-piling at the heel, the pressure increases less rapidly than the hydraulic slope. With no piling, and with piling at both heel and toe, the pressure increases more rapidly than the hydraulic slope.

10.—With sheet-piling at the heel, the flow of greatest density approximates the shortest distance from the end of the piling to the toe of the structure.

11.—The center of pressure, with no piling and with piling of any length at the heel, is $\frac{L}{3}$, measured from the heel of the dam. With piling at both heel and toe, the center of pressure is $\frac{5\,L}{11}$ from the heel of the dam.

12.—For the condition of no piling, the total pressure (in pounds) exerted on 1 lin. ft. of floor is:

$$P = 62.5\ b\ s + 62.5\ c\ (d^2 - 1).$$

13.—For the condition of impervious piling at the heel, the total pressure, in pounds, on 1 lin. ft. of floor is:

$$P' = [62.5\ b\ s + 62.5\ c\ (d^2 - 1)]\ k\ p.$$

14.—Piling at the heel of a dam, to be effective, must be tight, very small leakage destroying its action.

15.—Piling at the toe of a dam should be loose, in order to prevent increasing the upward pressure on the floor of the structure.

16.—An impervious cut-off wall of comparatively shallow depth, say 5 ft., at the heel of the structure will greatly increase its stability by reducing the upward pressure on the floor.

17.—Variation in the weight or downward pressure against the floor of a dam has little effect in changing the intensity of the upward hydrostatic pressure.

18.—The law of seepage or underground flow cannot be ascertained by treating an area as a unit. It can be best studied by breaking the area up into very small elements.

19.—The law, $P = a\,10^{-kx^n}$, when corrected for gravity, will probably apply equally to pressures in a vertical or horizontal plane.

ACKNOWLEDGMENTS.

The writer wishes to express his thanks to H. W. King, M. Am. Soc. C. E., for his valuable suggestions and assistance, to Professor Theodore R. Running for his timely assistance in solving the equations, and to Mr. Raymond A. Hill for aiding in the operations of the investigation.

DISCUSSION

Mr. Muckleston.

H. B. MUCKLESTON,* M. AM. SOC. C. E. (by letter).—This very interesting paper is most valuable, especially the curves presented as the result of actual experiment, as compared with those derived from purely theoretical investigation. The problem is susceptible of rigid mathematical analysis, if certain assumptions are made. These are: First, that the permeable base extends to an infinite distance in each direction in a horizontal plane; second, that the depth of the stratum is infinite; third, that it is uniform in permeability throughout and in any direction; and fourth, that the flow is capillary. Under these conditions, if a cut-off wall is considered as existing under the center of the impermeable base, of any depth, a, and the base width is $2b$, then the contours of equal pressure are the series of confocal hyperbolas:

$$\frac{x^2}{\cos.\ \beta} - \frac{y^2}{\sin.\ \beta} = c^2$$

where

$$c^2 = b^2 - a^2$$

and the lines of flow normal to them are the series of confocal ellipses:

$$\frac{x^2}{\cos.h\ \alpha} + \frac{x}{\sin.h\ \alpha} = c^2.$$

It is not necessary for the cut-off wall to be at the center, but if it is placed anywhere else, the equivalent depth at the center must be calculated from the equation.

It will be interesting to consider why the experimental results differ so widely from the theoretical. In the first place, the areas exposed to pressure between the ends of the box and the toe and heel of the experimental dam are very small in proportion to the base width of the dam; second, the depth of the permeable stratum is small compared to the base width; and third, the tail-water surface was somewhat above the sand level, whereas the theoretical hypothesis requires it to be at that surface.

The first and third conditions are probably responsible for the observed entry and exit heads, and the second is the cause of the peculiar shape of the pressure curves. The latter is the more noticeable when the experiments with the cut-off wall are considered, especially in those with the 3-ft. wall, where the throttling effect of the narrow passage is clearly seen. This effect is evident in all the plotted experiments, and it is very probable that had the observed pressure points been more closely spaced, island pressure contours would have been detected, for example, in Fig. 2, Exp. No. 38, Obs. No. 4, April 19th, 1914, between Points 19 and 29.

* Calgary, Alberta, Canada.

Mr. Muckleston.

Another effect of the first condition is noticed most strongly in Fig. 7, Exp. No. 20, Obs. No. 3, March 24th, 1914, where the pressure contours up stream from the cut-off are seen to be nearly parallel and approximately horizontal. The sharp downward curvature of the 2.50 contour is also noticeable, and is probably due to its very close proximity to the foot of the wall and the constricted opening under it.

Although the assumed conditions of the theoretical calculations are probably very far from those obtaining in actual practice, it is believed that the conditions of the experimental determinations are about equally far in the opposite direction, the truth lying somewhere between them.

Mr. Travell.

WARREN B. TRAVELL,* ASSOC. M. AM. SOC. C. E. (by letter).—This interesting paper bears directly on a question which is not only very important, but concerning which prominent engineers of the present day have radically different opinions—the question of uplift on the base of a concrete or masonry dam of the gravity type.

There is no doubt that, in the past, many dams have been built without any allowance having been made in their calculations for uplift, which is equivalent to taking the upward pressure on the base of the dam as zero, although a few engineers are insisting that the uplift should be taken at 100%, or full hydrostatic pressure.

These experiments constitute a valuable addition to our scanty knowledge of the subject, but it must be admitted that they were made on a rather small scale, and it is to be hoped that they will be added to by others, so that before long sufficient data will be furnished whereby engineers may come to an agreement in this matter.

It is noted that, in his experiments, the author used three different lengths of bases, namely, 4 ft. 3 in., 6 ft. 3 in., and 8 ft. 3 in., and on these short lengths as a foundation, he proceeds to draw conclusions applicable to all lengths of bases up to 100 ft.

The values of the constant, b, in the formula deduced for pressure, are determined to be 1.49, 6.13, and 24.78, for these three base lengths, and from these data, values of b up to 2 587 are derived. This appears to be equivalent to attempting to draw a curve having given only three points in that curve. The length of the curve thus given is the difference between 24.78 and 1.49, or 23.29 units, and this curve is then extended beyond the farthest given point to a length of 2 562 units. In other words, the curve is extended to a distance 110 times the determined length.

In the first place, three points are not sufficient to determine a curve of this kind, even for the distance between these points, and the extension of the curve thus found, especially when carried out to such a length, is interesting as the record of a guess, but is hardly entitled

* New York City.

Mr. Travell.

to a place among scientific data. Some of the greatest engineering disasters have resulted from the drawing of extended conclusions based on limited tests, and too great emphasis cannot be laid on the warning against such practice.

When frequent repetitions of an experiment are made under the same conditions, the uniformity of the results determines largely the degree of confidence to which such experiment is entitled. Examination of the tabulated pressure heads, given in Table 2 (Plate XV), apparently shows considerable variation for experiments conducted under similar conditions. For instance, in Experiment No. 29, Observation No. 1 was made with water at a height of 2.46 ft. above the base, and, in Observation No. 2, this was slightly less, or 2.44 ft. Yet the pressure heads given in the latter observation are as much as 36% greater than those given in Observation No. 1.

Regarding the curves for upward pressures, without sheet-piling, as shown in Figs. 9, 10, and 11, it is not clear to the writer why there should be about 80% of the 5-ft. head at the heel of the 4.25-ft. and 8.25-ft. dams and only 58% at the heel of the 6.25-ft. dam. It would seem that this figure should be practically constant for any given head, irrespective of the length of base.

Also, in Figs. 12, 13, and 14, showing pressures with different lengths of sheet-piling at the heel, it appears strange that, comparing the curves for the 5-ft. head, the pressure should increase from 49% of the head for 1-ft. sheet-piling to 66% for 2-ft. sheet-piling and to 76% for 3-ft. sheet-piling. As the sheet-piling was made longer, a decrease in pressures would naturally be expected, rather than an increase as shown in these curves.

It would be of great value to engineers if experiments similar to these were made in connection with the actual building of some masonry or concrete dams of the gravity type. Naturally, there would be a wide variation in the results of such experiments, depending on the porosity of the underlying foundation, the presence of seams in a rock foundation, the density of the concrete, and many other causes, but data thus obtained and given to the Profession would eventually settle the debated question of uplift.

Mr. Elliott.

MALCOLM ELLIOTT,* ASSOC. M. AM. SOC. C. E. (by letter).—For several reasons, the equations developed from this series of experiments do not seem to be suitable for general use in determining the upward pressure on the base of a dam built on sand foundation.

There is no known law of physics or hydraulics which would indicate that the pressures under a dam will be expressed by an equation in the form of $P = 62.5\ [bs + c\ (d^s - 1)]$. The author has measured the pressure on the model dam, platted the points, and drawn through them a curve which he finds is approximately the graph of the equation

* Louisville, Ky.

Mr. Elliott.

stated. So far as the writer knows, there is no reason that the pressures under a dam should be expressed by the curve of the law of error, and the fact that, within certain limits, the pressures are approximated by this curve should not be taken to indicate that the equation is a general expression for the pressure for all heads and floor lengths.

The utmost that can be said for the author's equation is that it gives fairly well the pressures which will occur in a model of the same dimensions and founded on the identical material used by him.

To demonstrate that the equation is not generally applicable, it might be well to cite some experiments carried on recently under the direction of J. P. Jervey, M. Am. Soc. C. E., Major, Corps of Engineers, U. S. Army, and described in an article* by Capt. W. A. Mitchell, Corps of Engineers, U. S. Army. The model used in these experiments was very similar to that used by the author. The floor length was 9 ft., made up of nine concrete slabs, 1 ft. wide, the joints of each being caulked. The heads were from 0 to 5 ft. Instead of having a flat bottom, the box containing the sand and the model dam was recessed so as to allow about the same space under the piling as under the slab. The piling was at the heel, and was 2 ft. long. In these experiments, three different materials were used, the following description of which is quoted from Capt. Mitchell's article:

"'Sand' means washed river sand screened through a ¼-inch screen.

"'Washed gravel' means ordinary river gravel washed and screened through a 2-inch, and retained on a ¼-inch, screen.

"'Gravel aggregate' means ordinary river-bottom mixture of gravel, sand, and mud at the site of Dam No. 14 [Ohio River], without any washing or screening whatever.

"'Alluvial soil' means ordinary sedimentary deposit on the banks of the river, as was obtained from the field near the apparatus."

The pressures transmitted through these materials are given in Table 8, which was compiled by the writer from Capt. Mitchell's data, the pressures having been converted from inches in the piezometer tubes to square feet of pressure curve, so as to afford a comparison with the pressures as computed from the author's equation. To obtain the actual pressure, in pounds, the quantities in Table 8 should be multiplied by 62.5.

The most striking point brought out by this comparison is the difference in pressures for different materials. This evidence does not seem to substantiate the author's Conclusion 6, namely:

"The porosity, effective size, and uniformity coefficient have little influence on the upward pressure exerted against the floor of a dam."

*Professional Memoirs, No. 31 (January–February, 1915), Corps of Engineers, U. S. Army, Washington Barracks, D. C.

Notwithstanding the difference in pressures shown by these two independent sets of experiments, due apparently to differences in porosity, etc., the writer, for practical purposes, would be inclined to accept the author's conclusion, because the influence of porosity, etc., if any, is not well understood, and cannot be determined without large-scale experiments at every dam site, and even then it would not be certain that the model used would duplicate the actual dam. For instance, the space under the model dam and the outlet through which the water flows are necessarily restricted in area, though the sand under a dam may be very deep and the outlet unlimited in extent. Who can say that these differences between "laboratory" and actual conditions do not materially affect the pressures?

It is probably because of the uncertainty as to the influence of porosity, etc., that, as a rule, the upward pressures are computed as if these factors had no influence. The fact, however, that these two sets of experiments give different pressures would indicate that an equation derived from experiments on a small-scale model and fashioned after no recognized physical law, cannot be considered generally accurate.

It is not necessary to call in outside evidence, however, to discredit the author's equations. They convict themselves. Extend the curve, in Fig. 16, for the 4.25-ft. floor, and it will be seen that for $\frac{H}{L} = 1.75$, the area of the pressure curve will be about 33 sq. ft., giving a pressure of about 2 060 lb. It will be granted without question that in no case can the upward pressure exceed the full head acting over the entire base. For $\frac{H}{L} = 1.75$, this would amount to about 1 950 lb. Thus, if the equation is true, we would have the surprising condition of an upward pressure greater than the head, and the water in the

Mr. Elliott.

tubes would stand higher than the water surface above the dam. For values of $\frac{H}{L}$ greater than those cited, the computed pressures increase very rapidly, and greatly exceed the total head. With the 6.25-ft. and 8.25-ft. floors, equally absurd results are obtained by extending the curves to $\frac{H}{L} = 1.7$ and $\frac{H}{L} = 1.6$, respectively.

It is the writer's opinion that the safest and most convenient assumption for the upward pressure and the location of its centroid is that there is a uniform loss of head from full head to zero throughout the distance the water travels in percolating under the dam. The distance traveled in the case of a dam with sheet-piling at the heel is approximately twice the length of the piling plus the width of the dam, and this sum divided by the head will give the hydraulic gradient or slope of the "piezometric line".*

Although this method may not be strictly correct, on account of making no allowance for differences in porosity, uniformity coefficient, and effective size, it will, so far as known, give results which are on the safe side. At the same time, the effects of porosity, etc., if any, are so vaguely understood that it is practically impossible for the designer to determine what they are.

Usually this method will give pressures greater than those recorded in the experiments referred to herein, but, in view of the uncertainties previously mentioned, it is not believed that the margin of safety will be unreasonably large, and the experiments are not conclusive enough to justify a departure from a method which, in the past, so far as known, has proved safe.

The action of water under dams is not limited to the upward pressure that it will exert on the base. A dam may be safe against overturning and sliding and yet fail on account of the erosion of the material under it, due to the flow of water through the porous material. This is perhaps the most uncertain of all conditions that must be considered in the design of a dam on a granular foundation. An investigation of the action of water under dams, to be thorough, should certainly deal, to some extent, with erosion.

Mr. Hays.

JAMES B. HAYS,† JUN. AM. SOC. C. E. (by letter).—During the past 15 months the writer has been studying along just such lines as those followed by Mr. Colman in his paper, and it gives him great pleasure to examine the results obtained by others, which, in a large measure, corroborate those obtained by himself.

A few months ago he began to write a paper on the subject for presentation to the Society, but press of other work and the desire to make further investigations have prevented its completion.

* The method is explained very clearly by W. G. Bligh, M. Am. Soc. C. E., in *Engineering News*, December 29th, 1910, p. 708.

† Boise, Idaho.

Mr. Hays.

The object of the writer's experiments was to determine the dimensions of an earthen dam to be constructed on a river bed of deep gravel. They were conducted in a large wooden tank, with an actual model of the proposed dam, constructed to scale, built on the gravel. Sheet-piling of various depths was interposed at different locations. Glass tubes communicating with the interior of the gravel mass showed graphically the pressures at the different points. The dam was placed about at the middle of the tank, and water was introduced on the up-stream side. Readings were taken showing the pressures at the different tubes for each of several different heads of water on the up-stream side. Seepage was also computed for each of the different heads.

In view of the writer's experience, he agrees with the author on the following points: (*a*), That there is a large loss of head where the water enters the gravel; and (*b*) that a practically uniform and relatively small loss of head per foot occurs horizontally through the main body of the gravel where its cross-section is uniform.

Regarding the loss of head where the water leaves the sand, or gravel, the writer's experiments and those of the author did not give the same results. However, this may be explained in either one, or both, of two ways.

The author's model was constructed so that the water entered the sand in a space 4 ft. wide, traveled under the dam in a space 5 ft. wide, and then, in the case of the 8-ft. floor, issued through a space 2 ft. 11 in. wide. It will be noted that the point of entry and the point of egress are constricted sections, relative to the space under the dam, which would naturally cause the water to be retarded, showing thereby a greater pressure head. The writer avoided these constrictions, and believes that his model more nearly represents the case in actual practice.

Then, again, where the shorter floor was used, the entire pressure head was not consumed. In some of the experiments using the longer sheet-piling, the base of the writer's model was longer in proportion to the head of water supplied, and without the constrictions mentioned, all the initial head was found to be consumed in friction, etc., before it issued from the down-stream side. Given a definite head of water, acting on a body of sand or gravel with known characteristics, a definite velocity will be produced. This, in turn, means a certain loss of head per linear unit and, by extending the length of the body of sand, or gravel, a point is reached where all the initial head is consumed. This is shown by the intersection of the hydraulic grade line with the body of the sand.*

* The writer would refer, in this respect, to Buckley's "Irrigation Pocketbook", p. 362, *et seq.*, and, also, to Professional Memoirs, U. S. Engineer Corps, Vol. VII, p. 32, *et seq.*, especially to p. 44.

Mr. Hays.

It is the writer's belief that the head lost by the water entering the sand might not have been so great had the width of the section been 5 ft. or more, instead of 4 ft. However, his own experiments show a large loss of head at the entrance of the water into the sand, or gravel. This, in all probability, represents the entry head and the velocity head.

The author's Conclusion 2 might be explained by the fact that with a shorter floor he has produced a steeper hydraulic gradient, hence a larger head is lost, creating the increased velocity necessary.

In regard to Conclusion 5, does the author mean that the pressure increases with the increase of depth, or the decrease of depth?

In general, aside from the points mentioned, the writer's experiments agree with those of the author, and though they do not reach the same conclusions on some points, this is explained, in all likelihood, by the difference in construction of the models.

Mr. Creager.

W. P. CREAGER,* M. AM. SOC. C. E.—The author deserves a great deal of credit for his work in connection with these experiments. The curves showing equal-pressure contours under his model dams will be of great interest to engineers and of material assistance in connection with further studies on the subject.

The speaker feels the necessity, however, of calling attention to the danger of applying information gathered from experiments on a small scale to the design of structures of much greater magnitude. In order to indicate the grave discrepancies which may be expected to result from the application, to large dams, of the author's formula for uplift, the speaker has computed from this formula the uplift on a dam with a 20-ft. base when subjected to a 30-ft. head of water. The author's formula follows:

$$P = 62.5\ bs + 62.5\ c\ (d^s - 1).$$

For this case, $H = 30$; $L = 20$; $S = 1.5$; $b = 278$; $c = 0.94$; and $d = 40.5$, from Table 6.

Therefore,

$$P = 62.5 \times 278 \times 1.5 + 62.5 \times 0.94\ (40.5^{1.5} - 1) = 41\,200.$$

The average uplift on the base is

$$p = \frac{P}{L} = \frac{41\ 200}{20} = 2\ 060 \text{ lb. per sq. ft.}$$

The average uplift head is $h = \frac{2\ 060}{62.5} = 33$ ft.

$$\frac{h}{H} = \frac{33}{30} = 1.10.$$

* New York City.

Mr. Creager.

From which it is seen that, for this example, the author's formula indicates a 10% greater average uplift head on the base than the head on the dam. This, of course, is an impossibility, as the greatest uplift head which could possibly obtain would be exactly equal to the head on the dam, and the average uplift head could equal the head on the dam only if there was an impervious barrier at the toe of the dam.

The speaker has calculated from the author's formula and plotted on the diagram, Fig. 18, the average uplift head, in terms of head

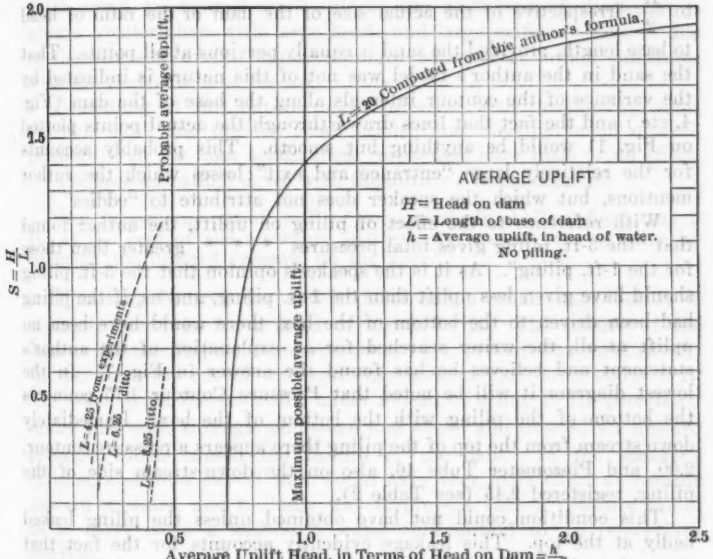

FIG. 18.

on the dam for a 20-ft. base and various values of S. He has also plotted two vertical lines representing the maximum "possible" uplift head and the "probable" uplift head for foundations of this type. The value, 0.5, for the speaker's probable uplift, was obtained by assuming an uplift head equal to H at the up-stream end of the base and diminishing uniformly to zero at the toe.

It is seen that the curve computed from the author's formula gives values of uplift at all points greater than the speaker's probable value, and for S larger than 1.4, it gives greater values than it is actually possible to obtain. Values of S greater than about 1.4 are not practical for dams with considerable uplift (unless built with a great super-elevation above water surface) and this does not alter the fact that

Mr. Creager.

the author's formula for such conditions is incorrect. There is, then, some question as to the accuracy of the formula for lower values of S.

The direct results from the author's experiments are plotted in dotted lines on the diagram. They all give values of average uplift less than the speaker's probable value, which is a condition quite likely to occur.

The speaker believes that the average uplift head on the base of an ordinary dam on a sand foundation without a cut-off is very close to $\frac{H}{2}$, irrespective of the actual size of the dam or the ratio of head to base length, provided the sand is equally pervious at all points. That the sand in the author's model was not of this nature is indicated by the variance of the contour intervals along the base of the dam (Fig. 4, etc.) and the fact that lines drawn through the actual points plotted on Fig. 11 would be anything but smooth. This probably accounts for the relatively large "entrance and exit" losses which the author mentions, but which the speaker does not attribute to "eddies".

With reference to the effect of piling on uplift, the author found that "the 3-ft. piling gives total pressures * * * greater than those for the 1-ft. piling". As it is the speaker's opinion that the 3-ft. piling should have given less uplift than the 1-ft. piling, and as, if the piling had been driven to the bottom of the box, there would have been no uplift at all, the writer searched for an explanation of the author's statement and believes he has found the answer in Fig. 7. In the lowest diagram it will be noted that Pressure Contour 1.75 connects the bottom of the piling with the bottom of the box. Immediately down stream from the top of the piling there appears a pressure contour, 2.00, and Piezometer Tube 46, also on the down-stream side of the piling, registered 2.45 (see Table 2).

This condition could not have obtained unless the piling leaked badly at the top. This leakage evidently accounts for the fact that the author observed greater uplift for 3-ft. piling than for 1-ft. piling, the latter being tight, as shown by Fig. 5.

Mr. Wegmann.

EDWARD WEGMANN,* M. AM. SOC. C. E.—The speaker must compliment the author and the University of Michigan on the scientific manner in which the experiments on the action of water under a model dam have been made and the results worked up. These experiments, however, were on a very small scale, and very different results may occur in the case of a dam having to sustain a pressure due to a large head. In these experiments, the greatest head was only about 5 ft. The base of the model dam was only 8 ft. 3 in., and the flow of the tail-water was affected by the end of the test box, which acted like a sheet-piling. The speaker does not consider it safe to apply to the case of a high dam some of the conclusions of the paper.

* New York City.

Mr. Wegmann.

The author found that the porosity, effective size, and uniformity coefficients had little influence on the upward pressure exerted against the dam. The speaker thinks that these factors would have a very material effect on such pressure, except for a very low head, in which case viscosity of the water, capillary action, etc., might prevent the water from exerting much upward pressure.

As an instance of the difference between the effect of high and low heads, attention is called to experiments with the flow through orifices. With small heads and small orifices the coefficient of discharge is always greater than with large heads and large orifices. This is due to the viscosity of the water, capillary action, etc., which interferes with the contraction of the jet.

Something of this nature might interfere with the flow of water through sand, and prevent small heads from exerting much upward pressure; but, for high heads, these resistances have little or no effect.

The speaker cannot agree with the author's Conclusion 16:

"An impervious cut-off wall of comparatively shallow depth, say 5 ft., at the heel of the structure will greatly increase its stability by reducing the upward pressure on the floor."

This may be true for a 5-ft. head and a small base, but it is certainly not true for a head of about 50 ft. The failure of the dam at Austin, Pa., on September 30th, 1911, proved that conclusively. In this case, the cut-off wall had only been carried down about 6 ft. The water from the reservoir, under a head of about 45 ft., percolated under this wall, through sandstone and shale, and exerted an upward pressure which caused the failure of the dam. In the speaker's opinion, a shallow cut-off wall would have very little effect as regards upward pressure, and the only way to prevent such a pressure would be to carry down a well-built, water-tight cut-off to an impervious stratum.

Recently the speaker has had some interesting experiences relative to the manner in which pressure may be transmitted under the base of a dam. In the case he has in mind, an earthen dam, about 25 ft. high, had to be constructed for about 250 ft. of its length on soft, marshy ground, underlain at the depth of 27 ft. by sand. The dam was 10 ft. wide on top. The up-stream side was sloped 2 to 1, but the slope was broken 14 ft. above the base by a berm 5 ft. wide. On the down-stream side a similar berm, 6½ ft. wide, was placed about 12 ft. above the base. Below this berm, the down-stream slope was made 2 to 1, but above it, the slope was only 1½ to 1. A core-wall, founded on a pile foundation, was constructed in the center of the earthen dam, and, in order to prevent the water from leaking under the dam, tight sheet-piling was driven on the up-stream side of the pile foundation.

Mr. Wegmann.

The dam would have stood successfully, if it had been founded on hard ground, but, for the marsh that had to be crossed, the plan adopted had the great defect of placing a considerably greater pressure on one side of the core-wall than on the other. In the former case the pressure was caused by the water and the saturated earth on the up-stream side of the core-wall. In the latter case the pressure was due to the dry earth on the down-stream side of the core-wall. The difference in pressure was transmitted through the marshy ground almost like the hydrostatic pressure of water, and forced the foundation platform of the core-wall and the sheet-piling down stream. The whole core-wall followed the same movement, and, when the speaker was consulted about what remedies should be adopted, the top of the core-wall had moved more than 3 ft. down stream.

A simple calculation showed the inequality of the forces acting on the two sides of the core-wall, and the speaker recommended an increase of 15 ft. in the top width of the dam and making the down-stream slope 3 to 1. These measures were carried out, and no further trouble has been experienced.

In the speaker's opinion, the proper way to have crossed the marsh would have been by constructing a homogeneous earth dike, having a greater slope on the down-stream than on the up-stream side, so as to offset the weight of water on the up-stream slope. The dam was bound to settle, and the only remedy for this was to continue filling until the soft material under it had been sufficiently compressed to bear the weight of the embankment.

If sheet-piling had been required to prevent leakage under the dam, it should have been driven, either at the toe of the up-stream slope, or on the center line of the dam, after the material under it had reached a state of equilibrium.

The speaker had a similar experience on the New York, West Shore and Buffalo Railroad, which showed how pressure was transmitted through soft ground. In this case two abutments, each 45 ft. high, had to be built for a 60-ft. plate-girder bridge which spanned Cedar Pond Creek, near West Haverstraw, N. Y. The ground at the site of the bridge was very similar to that on which the dam just mentioned had to be constructed. A long embankment, 45 ft. high, carried the railroad from the south side of the valley to the south embankment. A foundation was prepared for this embankment by corduroying the ground with two courses of round timber. On the north side of the bridge, only a short embankment was required. Both abutments were built on pile foundations.

When the toe of the south bank had about reached the south abutment, the weight of the embankment, although well distributed by the corduroy timbers, caused a pressure on the soft ground, which

forced the piling toward the creek. A similar movement occurred in the north abutment. The displacement of the two abutments, which reduced the original span by about 1½ ft., was due partly to scouring in the creek bed, which increased the depth of water from about 2 to 6 ft. Mr. Wegmann.

The moving of the abutments was stopped temporarily by bracing one against the other by 60-ft. piles, bolted together in pairs, tip to butt. A permanent bracing of 12 by 12-in. timbers, looking like an inverted roof, was then placed between the abutments, the peak resting on a crib sunk half way between them. Further scouring was prevented by driving sheet-piling above and below the abutments. The space between the two rows of sheet-piles was filled with stones. After the work had been completed, the temporary bracing was removed.

No further trouble was experienced with the abutments, and for many years they were held safely by the bracing described. The speaker understands that some changes or repairs have recently been made to the abutments, but he does not know their nature.

W. R. BALDWIN-WISEMAN,* ESQ. (by letter).—On page 430 the author has summarized the work of a few of the more important investigators of this subject; but, on a subject about which there are such extreme variations of opinion, it would have been better to have given a more detailed list. Schlichter† supplied a much more complete one, and the writer has given fuller details in the three following papers: "The Flow of Underground Waters,"‡ "Statistical and Experimental Data on Filtration,"‖ and "The Influence of Pressure and Porosity on the Motion of Subsurface Water."¶ Incidentally, another aspect of the subject is dealt with in "The Influence of the Thickness of the Pipe Wall on the Rate of Discharge of Water from Minute Orifices Piercing the Pipe."** Mr. Baldwin-Wiseman.

A very careful investigation of the subject has also been undertaken, and full references to other work are given, by J. Versluys in "Le Principe du Mouvement des Eaux Souterraines."††

The subject has been dealt with by the writer in "Statistical and Experimental Data on Filtration" (quoted previously), more particularly on pages 20 to 40, 55 to 61, and 127 to 130.

Data in the writer's possession, but as yet unpublished, show that the rate of interstitial flow and of loss of pressure are largely dependent on the material of the sand grains, on their angles—that is, whether

†† Published in Amsterdam in 1912.

Mr. Baldwin-Wiseman.

they were formed by subaerial or submarine denudation—and on the relative homogeneity of the sand mass; and the results of experiments conform more closely to an arbitrary law when the sand grains composing a mass are of fairly uniform size than when the constituents of the mass are heterogeneous, even though the mean diameter of the grains of the mass, when determined by a size analysis, may be almost identical with that of the uniform or graded sand. This point is well illustrated in Fig. 2 of the paper "Statistical and Experimental Data on Filtration". In that paper the writer has endeavored to represent these factors of roughness, angularity, etc., by a term which (for lack of a better one) has been called the thickness of the ideal film, not because such a film exists, but because it is a facile conception, and, as will be seen by consulting the table on page 33 of that paper, sands with practically the same porosity have ideal films, varying in the ratio 1:0, 1:7 and 0:4. So much for the velocity of interstitial flow. From unpublished investigations the writer has found that the greatest loss of pressure occurs in interstitial passages which have extreme and rapid change in cross-section.

The writer concurs entirely with Conclusion 1, as it is in agreement with conclusions succinctly stated on page 319 of his paper "The Flow of Underground Water",* and are well illustrated in the diagrams, *a* and *b*, on the same page; and they are fully confirmed by later experiments (not yet published) with graded and natural sands similar to those described in "Statistical and Experimental Data on Filtration".†

The writer also agrees with the substance of Conclusions 2, 3, and 4, as his own work has led him to similar conclusions, but he cannot agree with the deductions of Conclusion 6, for reasons already detailed herein. This, however, is doubtless due to the method of arriving at the effective size and uniformity coefficient, a subject on which the writer has already expressed an opinion and indicated better methods in his paper on filtration.

Mr. Oakes.

JOHN C. OAKES,‡ M. AM. SOC. C. E. (by letter).—This paper is of particular interest to those engaged in the design and construction of river improvement works.

In the writer's opinion, the model used in the experiments might have been improved by increasing its size, giving greater space beneath the sheeting, and more room for the escape of tail-water. The contraction beneath the sheeting, and the short distance between the ends of the platform and box, may have had considerable effect on the resulting pressures.

As might be expected, perhaps, the data in Tables 1 and 2 (Plates XIV and XV) show some inconsistencies which are more or less

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXV.

† *Minutes of Proceedings*, Inst. C. E., Vol. CLXXXI.

‡ Major, Corps of Engrs., U. S. A., Louisville, Ky.

puzzling. For instance, Tubes 2, 5, and 8 had their entrances at practically the same level, yet in some experiments the height of the water in Tube 8 was greater, and, again, in other experiments, much less than in Tubes 2 and 5. In Experiment No. 1, Observation No. 2, the values for Tubes 2 and 8 are, respectively, 0.50 and 0.93, yet, in Experiment No. 3, Observation No. 3, the values are 3.43 and 2.86. Mr. Oakes.

Figs. 9, 10, and 11 show pressure curves for different heads and different lengths of base. For a 5-ft. head, the pressure at the heel, with bases 4.25 and 8.25 ft. long, is greater than that for the base 6.25 ft. long. There is no logical reason for such a difference, and every reason why the pressures at the heel, under the conditions shown, should have been approximately the same; if any difference was to be expected, it would seem that the pressure should have been less for the shortest base, increasing to greatest for the longest base, on the theory that the slope of the pressure curve would be greatest when the path is shortest.

Figs. 12, 13, and 14 show pressure curves for the base 8.25 ft. long, with sheeting 1, 2, and 3 ft. long, under the heel. These curves show the smallest pressure at the heel when the shortest piling was used, and the greatest pressure when the longest piling was used. This is exactly the reverse of what should have been shown. The points plotted for Tubes 22, 26, 30, 33, and 36, for 2 and 3-ft. piling, are almost exactly in the same location for each case, and the pressures in Tube 16 alone show reduction for the 3-ft. piling, and there is an increase for Tube 46 for the same piling. By comparing Figs. 11 and 12, it will be noted that the pressures are very much reduced by using 1-ft. piling, particularly with the greater heads, and, logically, the longer piling should reduce the pressures still further.

These inconsistencies can probably be explained by the fact that sufficient time was not allowed to develop the pressures which should have been developed by the various heads recorded, and that there was some leakage through the sheeting. The author does not state how the head was held, but has mentioned that the time allowed for the head to adjust itself was not less than 2 hours. It seems probable that this time was not sufficient, otherwise it is difficult to account for the results. The author would have obtained much better and more consistent results if the head had been maintained at definite heights for 6 hours or more before readings were made.

However, the illustrations showing lines of equal pressures—Figs. 2 to 8, inclusive—are very interesting and instructive. They appear to confirm previous assumptions of the loss of head throughout the length of flow, and the effect of sheet-piling in increasing the length of the flow lines.

Mr. Oakes.

W. G. Bligh, M. Am. Soc. C. E., has stated* with reference to sheeting under dams, as follows:

"It has been ascertained experimentally that the value in increase of length of percolation due to a vertical obstruction is double that beneath a horizontal apron, for the reason that the percolating current travels down one side of the obstructing curtain wall and up the other."

The writer believes that this principle has been accepted, generally, for determining the length of travel for water under dams, when sheet-piles have been used. From the illustrations previously mentioned, it seems that a more conservative and correct length of flow would be obtained by taking the length of the sheeting below the river bed, plus the distance from bottom of sheeting to toe of base.

The writer cannot agree with the author's conclusions that the porosity, effective size, and uniformity coefficient have little influence on the upward pressure.

Other writers have shown the error in the author's equations for the pressure curve and for total pressures under the dam.

The most important of the author's conclusions, and the ones to be borne in mind by designing engineers, are that sheeting at the heel of the dam reduces the pressure under the floor, and that sheeting at the toe increases it; that sheeting at the heel of a dam, to be effective, must be tight (very small leakage destroying its action); and that sheeting at the toe should be loose in order to prevent increasing the upward pressure on the floor of the structure.

Although the academic discussion of pressures under a dam on sand foundation is of interest, the rules and conclusions deduced from experiments on models must not be allowed to affect too greatly engineering practice in the designing of actual structures. The use of the model in this case introduced several conditions which do not exist under actual structures, such as practical uniformity of sand, limitation of escape of seepage by bottom, sides, and end of box, and contraction under sheeting.

Practical rather than theoretical considerations are of the greater importance, because the conditions which the experimenter is able to obtain with a model can never be obtained in the field. For instance, it is noted that the author used a pressure on the sand under the platform of from 125 to 640 lb. per sq. ft. It may be that such pressures are developed under some dams on sand foundations, but such cases will be exceptional. Very seldom, if ever, will masonry dams or weirs be designed to rest directly on sand without supporting piles. Certainly, in river work, no one would think of building such structures on sand without using both round and sheet-piles, in which case there would be practically no pressure on the sand. If the bed of the founda-

* *Engineering News*, December 29th, 1910, p. 709.

tion is below the water level, and pumping is required, there will be a small space between the base of the masonry and the sand, caused by erosion by the flow of water from under one block of masonry while the next one is being placed. In other words, the structure is ordinarily supported wholly by the piles, with almost a certainty that there will be a space between the sand and the masonry. Under such circumstances, any upward pressure that develops under the dam will be uniform from the sheet-piling to the toe, and will depend on the tightness of the sheeting and the ease of escape below the dam, rather than on ideal laboratory conditions obtained with a model. Mr. Oakes.

Another practical consideration which must not be lost sight of is the difficulty, almost amounting to an impossibility, of obtaining a tight sheeting, unless excavation is made to the full depth and an impermeable wall is constructed. The writer is firmly convinced that not more than once in a hundred times will driven timber sheeting be tight. When interlocking steel piles are used, there is grave danger that the piles may be forced apart while being driven, destroying the effectiveness of the sheeting. Even when this does not occur, there will still be considerable leakage through the joints between the piles, particularly when first driven. Considering, therefore, that a tight sheeting is a very rare occurrence, and that most dams and weirs on sand will be supported on piles with a space between the masonry and the sand, full upward pressure must be assumed. Furthermore, if dams to be built on sand are properly designed for stability against sliding and overturning, and seepage is reduced sufficiently to prevent piping and blow-outs, by a proper combination of sheeting and width of base, the structures will be found, in most cases, to be capable of withstanding full upward pressure. Typical designs of certain structures, however, such as reinforced concrete dams, and the masonry bases of movable dams, will not provide sufficient weight to withstand such pressure, and the weight must be increased, or some other means, such as hold-down piles, must be used to insure stability.

Among the more important structures being built at the present time on sand foundations are the locks and dams in the lower Ohio River. These works are being built to provide a navigable depth of 9 ft. throughout the length of the Ohio. Movable dams (Chanoine) are being constructed with normal lifts of from 7 to 9 ft., and maximum lifts as great as 16 to 17 ft. The greater lift at a dam occurs when the lower pool has been lost, due to the maneuvering of the next lower dam, when there will be low water below and an upper pool above the dam under consideration. The locks are 600 by 110 ft., inside dimensions (usable). All the locks and dams below Louisville, twelve in number, must be built on sand foundations, and the means of preventing failure of these works, due to upward pressure, piping

Mr. Oakes.

and blow-outs, and undermining by erosion below the dams, have been of the greatest interest and anxiety to those engineers who are responsible for the design and the construction of these works, which are exceptional in size of locks, lengths of dams, and heads to be withstood by river structures on sand foundations.

During the last three years the writer has had charge of the construction of the Ohio River Locks and Dams Nos. 43 and 48, both being built on sand foundations. The typical plans provide for a timber sheeting 25 ft. deep, of Wakefield piles, to be driven under the toe of the land- and guide-walls, under both toe and heel of the river wall, and under both up-stream and down-stream edges of the sills. The plans originally called for the same kind of piling under the heel of the dam. All structures are supported on round and sheet-piles.

After the difficulties of driving timber piles to form a tight sheeting had been thoroughly proved, and full consideration had been given to the insecurity of structures on sand foundations, a line of interlocking steel sheet-piling, 40 ft. long, was substituted for the Wakefield piling under the dams, and a heavy lock floor, 4 ft. thick, held down by round piles, replaced a light floor, 18 in. thick, without piles. The writer has watched the construction of these two works for three years, has noted the careful efforts to produce a tight sheeting with the timber piles, and has concluded that it is almost impossible to do so. This confirms his previous experience and that of several other engineers with whom he has discussed this matter. Certainly, in the design of structures on sand foundations, the assumption cannot safely be made that a tight sheeting can be provided by driving timber sheet-piles. Better results can be obtained with steel piles, but one never knows when the sheeting is disrupted in driving, and there is always more or less leakage, even without disruption.

In the same manner the writer has watched the placing of concrete, and in no case has he found, on the works under discussion, that the concrete rested on the sand after sufficient time had been given it to set. The bed of the foundation of the various parts of these structures is about 10 ft. below low water. Construction has been carried on within coffer-dams, and during stages of the river from low water to 14 ft. above it. Owing to the permeable nature of the material, there has always been considerable percolation, which has required pumping to keep the pit sufficiently clear of water to enable construction to proceed. The water escaping from under the concrete already placed carries away the fine material directly under the concrete, leaving a space between it and the sand through which the transmission of pressure will be direct, and, consequently, any pressure which may be developed will be uniformly exerted over the whole base of the structure.

Mr. Oakes.

However interesting it may be to know what the upward pressure under a dam would be under ideal conditions (assumptions), such as tight sheeting, uniform material under dam, uniform weight on sand, etc., it must be borne in mind that such conditions will never be obtained throughout the length of the dam as actually constructed; that the computed pressure based on those assumptions will be the least possible pressure; and that the dam must be designed to withstand at all sections the greatest possible pressure, which will be, under ordinary circumstances, that due to the full hydrostatic head.

Mr. King.

H. W. KING,* M. AM. SOC. C. E. (by letter).—Mr. Colman deserves great credit for having made a careful and systematic study of an important engineering problem of which but little is known. The engineer is confronted with this problem whenever he undertakes the design of a dam, and especially a dam of the type commonly constructed on earth foundations. At present there seems to be no uniformity of practice among engineers in allowing for upward hydrostatic pressure. Cases might be cited in which no allowance was made for such a pressure, and in other cases allowance has been made for a pressure equal to that exerted by the total head under the entire base of the dam.

The point at which the resultant pressure under a dam should be applied is an important consideration, as is also the effect of sheet-piling on upward pressure and in reducing seepage. The author's experiments throw much light on all these important points.

The writer was in close touch with Mr. Colman during the progress of these experiments, and there is no doubt that each detail was worked out with great care and thoroughness. It does not seem probable that many more data could be secured from a series of experiments of this nature than were obtained by Mr. Colman. Some inconsistencies appear in the results, but, in a great measure, these may be explained, and do not necessarily detract seriously from the value of the experiments as a whole.

The criticism has been made that the scale of the experiments was too small, and that a larger model would give more reliable results. This may be true, but Mr. Colman's model was approximately 10 ft. high and 16 ft. long, and a much larger one would hardly be feasible. Experiments on a larger scale must be made on existing dams, and it should be possible to obtain much valuable information in this manner. Such data, however, must necessarily be incomplete, and experiments on models like Mr. Colman's will be valuable in interpreting and extending them.

One important point brought out by these experiments was that sheet-piling, to be effective in preventing upward pressure, must be

* Ann Arbor, Mich.

Mr. King. absolutely water-tight. The importance of this fact was not realized early in the investigation, and proper precautions were not taken with the first piling to prevent leakage. It was found that the effect of such piling could scarcely be noticed. This condition was changed immediately, however, when the piling was made impervious.

The effect of tight piling may be seen from Figs. 11 and 12. With no piling, for a depth of water of 5 ft. above the dam, the upward pressure head just below the dam is approximately 4 ft., and, with 1-ft. sheet-piling at the heel of the dam, it is 2.5 ft.

Unfortunately, the relation between length of piling and total upward pressure cannot be seen from these experiments. There can be no doubt that the upward pressure must decrease as the piling is lengthened, but, from Figs. 13 and 14, the opposite appears to be the case. This anomaly the writer believes is due to leaky sheet-piling. In spite of the fact that every apparent precaution was taken to prevent leakage, it is probable that some water was able to find its way through the piling, and thus in a measure nullify its effect.

This principle has an important practical bearing on dam construction. It is a common practice to drive a row of sheet-piling at the heel of a dam. There is no kind of sheet-piling that can be considered water-tight, especially when the usual difficulties encountered in driving are taken into consideration. It would appear, then, that such piling has little or no effect in reducing upward pressure under the dam. The writer is of the opinion that a good impervious concrete cut-off wall of moderate depth will have a more beneficial effect in this regard than any quantity of sheet-piling.

The experimental data on seepage appear to be a little conflicting. The writer believes, however, that a cut-off, to be effective in reducing seepage, must be water-tight and extend into an impervious stratum. Frequently, the seepage losses through the banks around a dam are a more important consideration than seepage under the dam.

The author submits a formula for determining the total upward pressure on the base of a dam. This formula has been shown in earlier discussions to be inapplicable in extreme cases. This is only to be expected, as the formula, which is derived from a small number of points, all in the lower limits, has no theoretical basis. No empirical formula of this kind can be used with real assurance beyond the range of the experimental data on which it is based.

It may be seen from Figs. 9 to 15, that, for any experiment, if a straight line is drawn from a point corresponding to the depth of water above the dam to the toe of the dam, this line will, in general, lie above the pressure line corresponding to this experiment. From this it appears that if the upward pressure on the base of the dam is taken as the hydrostatic pressure due to one-half of the head against

the dam, the assumption will be safe. It seems reasonable to assume that this rule should apply to higher heads and larger dams. Mr. King.

An examination of Table 5 shows that, with sheet-piling at the heel of the dam, the upward pressure is equal to about three-tenths of the total hydrostatic pressure. The experiments with 2-ft. and 3-ft. piling would doubtless show a total pressure less than this, if there had been no leakage through the sheet-piling. The author has pointed out the fact that an impervious cut-off at the toe of a dam will increase the upward pressure and move the point of application of the resultant pressure down stream.

Using the author's notation, in which H, L, and P represent, respectively, the head of water against the dam, the length of cross-section of the base of the dam, and the total upward pressure per unit length of dam, the following simple formulas should be safe guides in determining upward pressure:

(1) With no cut-off at the heel of the dam or with ordinary sheet-piling,

$$P = \frac{62.4}{2} H L = 31 H L;$$

(2) With an impervious cut-off at the heel of the dam,

$$P = \frac{62.4}{3} H L = 21 H L.$$

The point of application of the resultant, P, is $\frac{1}{3} L$ from the heel of the dam.

Both samples of sand used in these experiments were comparatively clean. It seems probable that a sand having the voids well filled with silt would show a smaller pressure. It would hardly seem safe, however, under any conditions, to assume a pressure smaller than that determined from these experiments, as earth in its natural state may not be of uniform mixture, and a seam of sand may be the controlling factor in producing pressure, rather than an average mixture of the material under the dam.

ROBERT E. HORTON,* M. AM. SOC. C. E. (by letter).—The writer had the pleasure of examining the apparatus and methods while this investigation was in progress, and has full confidence in the results, as far as they go. The data are well presented; the deductions are made in a logical and orderly manner; and the paper is an original and valuable contribution to experimental hydraulics. The writer fully realizes the labor and difficulties involved in prosecuting original investigations, and intends no criticism when he says that these results should be confirmed and extended by further studies. Mr. Horton.

* Albany, N. Y.

Mr. Horton. In view of the great present-day importance of hydraulics, in water-power, water supply, irrigation, drainage, sewerage, and navigation—matters vital to life and indispensable to commerce—efforts should be made to provide additional hydraulic laboratories and means to conduct experimental hydraulic and hydrological work therein along much broader lines than ever heretofore attempted. The average layman has a misty conception of the functions of a hydraulic laboratory; the average engineer probably looks on it as a place where neat little experiments are performed to illustrate to students the flow of water over weirs or through orifices under ideal conditions. That is a useful function, but much greater service may just now be rendered by providing means whereby life-size experiments on a wide variety of subjects may be carried out. There is hardly a subject in the domain of formal hydraulics that does not need a great deal of large-scale experimental work, and there are many subjects which have been scarcely touched experimentally; such, for example, as the phenomena of the standing wave. Furthermore, there are several subjects —in connection with dams, for example—in relation to which present-day design is based largely on very arbitrary assumptions.

The phenomena of the causes of floods, low-water flow of streams, yield of wells, evaporation, and many other hydrologic subjects could be investigated to great advantage in a good hydraulic laboratory, yet such laboratory studies have never been undertaken to any extent.

Mr. Colman's paper is a good example of a clean-cut and valuable investigation, capable of being carried out at moderate expense in a hydraulic laboratory. Even on this subject, however, more could have been accomplished almost in direct proportion to the time and means available. For example: experiments on dams with longer bases appear to be desirable; and valuable results could be obtained by conducting experiments on earth dam sections with cores.

The experimental results given suggest that, for an earth dam of homogeneous material with an impervious core, and on a permeable foundation, the water under the part of the dam down stream from the core would rise by static pressure and the down-stream portion of the dam might thus be saturated to the same, or nearly the same, degree if the core was absolutely impervious as if it was somewhat permeable. If, on the other hand, the dam is on an impervious foundation and the core is somewhat permeable, the water just below the core will stand at a height below that in the pond, dependent on the resistance to flow afforded by the core and the freedom of outflow of the percolating water. Apparently, the more permeable the material on the down-stream side of the core the less will be the degree of saturation of the down-stream face of the dam.

As regards conditions within the portion of an earthen dam up-stream from an impervious core, experimental work is also needed

Mr. Horton.

HYPOTHETICAL CONDITIONS WITHIN EARTHEN DAMS.

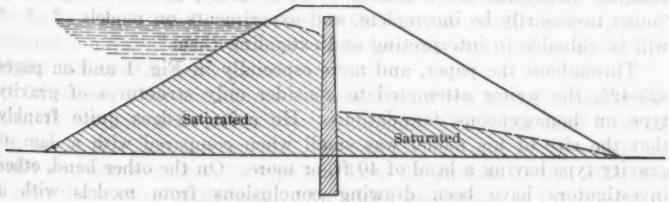
B.-NON-PERMEABLE FOUNDATION, SEMI-PERMEABLE CORE. DOWN-STREAM SIDE COMPACT.



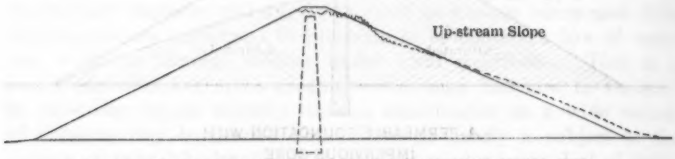
C. NON-PERMEABLE FOUNDATION SEMI-PERMEABLE CORE. DOWN-STREAM SIDE OF OPEN TEXTURE.

FIG. 19.

Mr. Horton.

to determine the best materials and their stability when saturated. These hypothetical conditions under earth dams are illustrated by Fig. 19. Confirmatory experiments are needed.

The failure of the Savage Reservoir, near Utica, N. Y., in September, 1902, was accompanied by a sloughing off of the up-stream face into the reservoir, as shown by Fig. 20.



CROSS-SECTION OF SAVAGE RESERVOIR DAM, NEAR UTICA, N.Y., SHOWING RELATIVE POSITION OF UP-STREAM SLOPE BEFORE AND AFTER FAILURE.

FIG. 20.

An incipient failure of a certain dam due to the slipping of the inner slope is reported, but it was checked by draining the water down below the opening left by the slip. Thus, it appears that the safe inboard slope of earthen dams needs experimental study.

These illustrations suggest a few of the many lines of experimental investigation needed in practical hydraulics.

Mr. Colman.

J. B. T. COLMAN,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read the discussions with much interest. As a result of the radically different opinions therein expressed, his own ideas have been made more lucid. A small part of the discussion is not closely allied to the subject.

At the present time, very few data pertaining to the hydraulics of existing structures are available. "Such data", as Mr. King states, "must necessarily be incomplete, and experiments on models * * * will be valuable in interpreting and extending them."

Throughout the paper, and more especially in Fig. 1 and on pages 423-425, the writer attempted to consider only structures of gravity type on homogeneous foundations. He acknowledges quite frankly that the size of his model was small when compared with a dam of gravity type having a head of 40 ft. or more. On the other hand, other investigators have been drawing conclusions from models with a capacity ranging from less than 1 cu. ft. up to 16 cu. ft. This model was approximately 16 ft. long, 4 ft. wide, and 10 ft. high.

The sands used were very uniform in analysis. Several samples, taken while removing them from the model, and afterward analyzed,

* Detroit, Mich.

showed almost identical results for each sand. At the same time, no indication of piping action was observed. Mr. Colman.

Before taking up the experiments, the ratio of the area exposed to pressure, the width of the dam, and the area at the toe, were carefully considered. It will be seen that the pressure curves show the same general form throughout. The high-pressure curves, in each case, for the 4.25, 6.25, and 8.25-ft. floors (Figs. 2, 3, and 4), start from the heel of the structure and slope forward in a direction that approximates the horizontal. The low-pressure curves, in each case, start from the toe and slope in a curve of similar form, but down stream from the structure. As might be expected, the latter curves are flatter for the shorter than for the longer floor length.

Again, attention must be called to the fact that there are no readings which would indicate a restricted entrance or exit. That which appears at first to be the result of insufficient exposed surface at the heel and toe of the structure is, as a matter of fact, the indication of the law sought. Unfortunately, Mr. Hays does not supply the data whereby he maintains that the published experimental work shows restriction of entrance and exit.

The difference in the readings of individual tubes is raised by Mr. Oakes, as shown by Nos. 2, 5, and 8, which are at the same elevation. In Fig. 21 the writer gives the leveling curves for these three tubes for Sand *B*. The method of plotting these curves is given on page 429. It will be seen that Tube No. 8 gives, for all three floor lengths, values less than those for Tubes Nos. 2 and 5. The same tube leveling curves for Sand *A*, with a single exception for Tube No. 2, hold the same relative position. That is, the lowest for all three floor lengths is Tube No. 8, then Tube No. 5; and the highest is Tube No. 2.

Throughout his work, the writer strove to forget the mathematical demonstration, as indicated by Mr. Muckleston, and given more fully by Parker* and others. This proof is very interesting, but is based on assumptions purely theoretical. One hardly needs to go into a discussion to show the weakness of a formula obtained as the result of the indicated operations.

Of course, when one admits the weakness of the mathematical equation, the objection to the tail-water standing above the sand level at the toe of the dam is removed. In practice, no one would expect to build a structure of gravity type and keep the surface of the tail-water just at the surface of the sand. An added precaution in this direction would rather detract from than add to the usefulness of the data.

The writer is very much gratified indeed that other investigators, working along similar lines, have obtained results which agree wholly

* "The Control of Water", by Philip & Morley Parker, Assoc. M. Am. Soc. C. E., pp. 279–299.

Mr. Colman.

or in part with Conclusions 1, 2, 3, and 4. It would seem that the partial disagreement of Mr. Hays indicates that he has worked with a small number of data, or with too few piezometer tubes.

It is hardly necessary to explain why the law of pressure, between certain limits, should resemble closely the curve of the law of error. In fact, there is no satisfactory mathematical proof that applies to the law of error itself. The point to be considered is that the writer, in attempting to determine a curve which would most closely fit the cases in hand, could find none that would approximate all points so nicely as the probability curve. It is hoped that other investigators, with more data at hand, may be able to determine a simpler curve, which can be solved directly.

Mr. Elliott and Mr. Creager state very correctly that, if the values of $\frac{H}{L}$ are increased to 1.75 and 1.4, respectively, the equation gives greater values than it is possible to obtain. It would seem to the writer that, for the time being, these two gentlemen lost sight of the fact that gravity-type dams on porous foundations are rarely constructed with a ratio of H to L greater than 1 to 2, and more often with a ratio of 1 to 5.*

In this instance, the curve was extended from three to seven times its practical limit. Judging from Mr. Creager's curve in Fig. 18, it would seem that the formula is not at fault for values of S less than unity. The writer was fully aware that his formula would not hold for structures on so-called impervious or semi-impervious foundations, into which classes structures with values of S greater than unity fall.

Mr. Oakes brings up the same question in a different form when he says, "For a 5-ft. head, the pressure at the heel, with bases 4.25 and 8.25 ft. long, is greater than that for the base 6.25 ft. long". It is very obvious that the pressure at all points is a function of the slope, that is, of both H and L. The 5-ft. head with the 4.25-ft. base is, as pointed out, above the working value of S. Under such a structure, if the action was continued, piping action would doubtless take place and later failure. The material difference in the percentage of pressure, Fig. 9, for the 3 and 4-ft. heads over the differences in percentage of pressure for the 1, 2, and 3-ft. heads, indicates the approach to the limit of the working value of S.

The writer purposely avoided the question of the effect of the sand coefficients and sheet-piling until he had disposed of the items of fundamental importance. Not that the effect of these coefficients is unimportant; but that, in experimental work, it follows rather than precedes the above.

* The reader is referred to the paper entitled "Dams on Sand Foundations: Some Principles Involved in Their Design, and the Law Governing the Depth of Penetration Required for Sheet-Piling", by Arnold C. Koenig, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 175.

Mr. Colman.

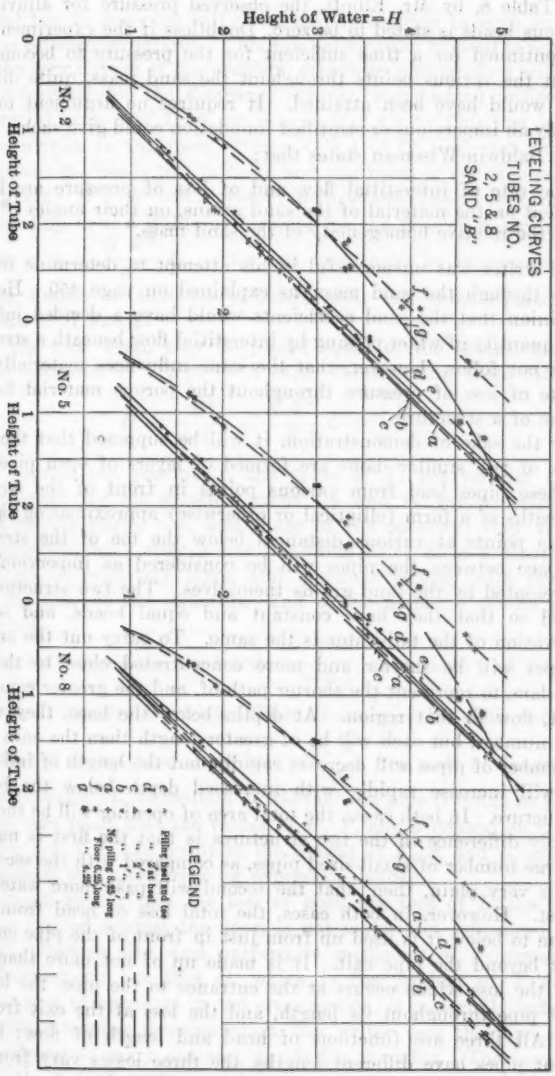


FIG. 21.

Mr. Colman.

In Table 8, by Mr. Elliott, the observed pressure for alluvial soil at various heads is stated to be zero. Doubtless if the experiments had been continued for a time sufficient for the pressure to become constant at the various points throughout the sand mass, quite different results would have been attained. It requires no argument to show that only an impervious or stratified foundation could give such a result.

Mr. Baldwin-Wiseman states that:

"The rate of interstitial flow and of loss of pressure are largely dependent on the material of the sand grains, on their angles * * * and on the relative homogeneity of the sand mass."

The writer was unsuccessful in his attempt to determine the rate of flow through the sand mass, as explained on page 450. He is of the opinion that the sand coefficients would have a decided influence on the quantity of water passing by interstitial flow beneath a structure. It does not follow, however, that the same influences materially alter the rate of loss of pressure throughout the porous material forming the base of a structure.

For the sake of demonstration, it will be supposed that the foundations of two similar dams are formed of layers of open pipes, and that these pipes lead from various points in front of the structure along paths of a form (elliptical or otherwise) approximating the flow lines, to points at various distances below the toe of the structure. The space between the pipes will be considered as impervious, and is represented by the sand grains themselves. The two structures are situated so that they have constant and equal heads, and so that the elevation of the tail-water is the same. To carry out the analogy, the pipes will be shorter and more concentrated close to the floor of the dam, to represent the shorter path of, and the greater concentration of, flow in that region. At depths below the base, they will be less in number, but each will be of greater length than the ones above. The number of pipes will decrease rapidly, but the length of individual pipes will increase rapidly with increased depth below the base of the structure. In both cases, the total area of opening will be the same. The only difference in the two structures is that the first is made up of a large number of small-sized pipes, as compared with the second.

It is very plain, then, that the second will pass more water than the first. However, in both cases, the total loss of head from above the dam to below it is used up from just in front of the pipe entrance to just beyond the pipe exit. It is made up of not more than three losses: the loss which occurs at the entrance to the pipe, the loss per foot of pipe throughout its length, and the loss at the exit from the pipe. All three are functions of head and length of flow; but, as different pipes have different lengths, the three losses vary from pipe to pipe. The velocity of flow in each pipe will adjust itself so that

the total loss in one pipe will equal that in another in each structure, and also between structures. This total absorption of head is necessary, from the very nature of the problem, otherwise piping effect will occur. Mr. Colman.

The formula for the discharge through sharp-edged orifices is of the form, $Q = m\,A\,\sqrt{2\,g\,h}$, or $V = m\,\sqrt{2\,g\,h}$.* This last equation may be written in the form, $V = m\,\sqrt{2\,g}\,\sqrt{H' - h''}$, where H' and h'' represent the heads just in front, and just back, of the pipe entrance, respectively. $H' - h''$ will represent the head consumed in entrance loss.

According to the Williams formula for the flow of water in pipes, the loss is $h_f = \frac{K\,V^n}{d^0}\,L$. The exit loss could be represented by a formula similar to that for entrance loss. All three equations are functions of H and L.

H, the total head, may be placed equal to the several losses, or $H = h$ entrance $+$ h pipe $+$ h exit. Substituting these values, we have:

$$H = \frac{V^2}{m\,2\,g} + \frac{K\,V^n}{d^0}\,L + \frac{V^2}{m'\,2\,g}.$$

As pointed out previously, the value of V, the velocity of flow, is very small for all practical cases; m and m' are constants, and depend on the angle, size, and shape of the opening; they vary but little, however, with size; g has the value 32.2; K is a constant; L, the length, is relatively large, and increases rapidly with the depth below the floor of the structure; and d, the diameter of the pipe, is very small.

Now, as V decreases, the fraction, $\frac{V^2}{m\,2\,g}$, decreases; and for small values of V, it approximates 0. Then $H = \frac{K\,V^n}{d^0}\,L$. This expression states that H is expended at the rate of $\frac{K\,V^n}{d^0}$ per unit of length over the entire length, L, regardless of whether the pipe is rough or smooth.

It is very plain that the values of K, V, and d depend on the sand analysis; but V is the result of the weight of K, d, and L, and takes a value such that the foregoing expression holds.

It would appear that the loss of head per foot of L, the upward pressure exerted against the floor, is not materially influenced by the porosity, effective size, and uniformity coefficient of a homogeneous sand foundation; but that Q, which is the product of V and the effective area of openings in the cross-section, is materially influenced.

In the foregoing demonstration, the writer uses the pipe analogy in an attempt to carry out and clarify his thoughts. The comparison

* Chapter 6, "Mechanics of Engineering," by Irving P. Church, Assoc. Am. Soc. C. E.

Mr. Colman.

has been briefly referred to by different writers, none of whom, however, to his knowledge, carries it through to a conclusion.

Attention might be called to the fact that this analogy is not quite parallel, in that the effective area of openings in the sand increases somewhat from the surface of the sand in the bottom of the reservoir to some point beyond the toe of the dam. This influence, then, would alter the value of V throughout the length of its course; it would increase its value at the entrance, cause it gradually to decrease throughout the length of flow, and decrease it at the exit. In the foregoing equation, the entrance loss would be increased, the loss of head per foot of pipe would have a gradually decreasing value throughout the length, L, and the exit loss would be decreased. This small secondary influence of a greater or less change of velocity, as between structures, can alone act to alter the form of the upward pressure curve.

Mr. Creager and others think that for a sand equally pervious at all points, the upward pressure on the base of a dam without cut-off approximates $\frac{H}{2}$, irrespective of the size or ratio of the head to the base length. Designers have used values for upward pressure ranging from zero to H over the entire base length, L. They also disagree as to the point of application of this upward pressure. Some have used $\frac{L}{3}$ as the distance from the heel to its center of gravity, and others have used values as high as $\frac{L}{3}$ from the toe. It would seem, the plotted curves and data make this point clear, as Professor King points out, that the upward pressure is somewhat less than $\frac{H\ L}{2}$, or:

$$P = 31\ H\ L.$$

It also shows that the point of application of this force is $\frac{L}{3}$ measured from the heel of the dam.

Turning to the condition of sheet-piling, the writer feels justified in stating that, in the case of Sand *A*, he had used reasonable precautions in placing the 1-in. lumber piling at the heel. The results were unsatisfactory. With Sand *B*, a single piece of sheet metal was in each case closely tacked to the box on the two sides and to the heel of the dam to form the sheet-piling.

It would seem that, as Mr. Travell points out, "As the sheet-piling was made longer, a decrease in pressure would naturally be expected". If the indicated data are influenced so markedly, as they appear to be, by very small leaks, surely it emphasizes the desirability of using an

impervious cut-off wall instead of sheet-piling at the heel of the structure. Mr. Colman.

It is not suggested that the use of an impervious, comparatively shallow, cut-off wall will reduce the flow, as some of those who have discussed the paper seem to assume; but that it will greatly reduce the upward pressure on the floor. The safety of a structure does not depend on the quantity of water that may pass through the sand foundation, but on the velocity and pressure head that may reach the exit layers of sand and wash away those particles.

Such a cut-off wall would concentrate the flow lines at its bottom, where no piping or washing action could take place. These lines, after passing the base of the cut-off, would spread out fan-like through an angle approximating a quadrant. This action would mean a rapidly increasing area of effective cross-section and a correspondingly reduced velocity of flow, with the accompanying loss of head. By altering the direction of flow, its concentration, and the resulting velocity of flow and loss of pressure head, where no removal of particles can occur, the upward pressure on the base of the dam is materially decreased, and its safety is proportionately increased.

The writer wishes to emphasize the point that an impervious cut-off wall of moderate depth at the heel of a structure will have more beneficial results than any quantity of sheet-piling.

All seem to agree that sheet-piling at the toe of a structure, if used, should be loosely driven.

Mr. Wegmann cites the failure of the dam at Austin, Pa., to refute the use of a cut-off wall, such as just outlined. The cross-section of this structure was of such a form as might be used on any moderately sound rock foundation, and was not designed for a porous foundation. It seems to the writer that the failure of this structure, the foundations of which were of stratified shale and sandstone, does not reflect on the point at hand.

The writer firmly believes that the effect of ordinary driven sheet-piling, either of wood or steel, as a cut-off for pressure head, is practically zero. The use of long-length, steel, sheet-piling and anchor-piles, similar to those cited by Mr. Oakes, in a low diversion weir, has come under his observation. In this case (the original head weir on the Tarlac Irrigation Project, Tarlac, Philippine Islands), with the foundation and weir complete, and with a head of perhaps one-fifth of that for which the structure was designed, piping action was going on. Needless to say, when a flood came, shortly afterward, the structure failed.

Paper No 1357

THE TWELFTH STREET TRAFFICWAY VIADUCT, KANSAS CITY, MISSOURI*

By E. E. Howard, M. Am. Soc. C. E.

With Discussion by Messrs. F. W. Green, L. J. Mensch, Howard W. Holmes, M. M. Upson, E. A. Slettum, L. R. Ash, John Lyle Harrington, and E. E. Howard.

Synopsis.

This paper describes the planning, the design, the equipment for, and methods of, construction, of a double-deck, reinforced concrete, trafficway viaduct, 2 300 ft. long, 60 ft. wide, and 120 ft. high, recently opened for traffic in Kansas City, Mo. Some special applications of general theories involved in the calculations for design are given, and summarized and classified costs are included. The features deemed of particular interest are the design of a large arch forming a portion of the structure, and the arrangement of the contractor's plant and equipment.

For convenience the paper is divided into the following parts:

1.—Introductory and historical.
2.—General description of structure.
3.—Loadings, specifications for, and methods of, design.
A. Investigation of columns.
B. Design of arch.
4.—Specifications for materials and workmanship.
5.—Equipment for, and methods of, construction.
6.—Quantities and costs.
7.—Personnel.

* Presented at the meeting of September 1st, 1915.

The description of features and details which may be grasped readily from an inspection of the accompanying illustrations is omitted.

1.—Introductory and Historical.

The Twelfth Street Trafficway Viaduct forms the principal part of the Twelfth Street Trafficway, a general municipal improvement designed to facilitate usual street traffic between sections of Kansas City, Mo., which are separated topographically. The total cost of the whole improvement, including land damages, was about $1 000 000, the viaduct structure costing about $650 000. The funds were provided by a portion of a general bond issue of $475 000, by assessments against a benefit district of special tax bills of $325 000, and by a contribution of $200 000 from the local street-car company in return for operating privileges over the structure.

The rather flat, level valley of the Kaw River, in Kansas City, locally known as the "West Bottoms", is about 1 mile wide, and is occupied by railroad yards, freight stations, warehouses, packing-houses, wholesale and manufacturing concerns, and the large stock yards interests, including a considerable percentage of the city's business. It lies at an elevation some 150 ft. below the principal residential, retail, and office building districts of the city, the break between the two elevations being rather precipitous bluffs and hills from 100 to 200 ft. high. Twelfth Street is the principal east-and-west thoroughfare of the city, and may be said to be a central axis, both with respect to the up-town part of the city, and the industries in the Bottoms. There have been only three routes for vehicular travel between these levels: the northern routes, requiring a diversion of about ½ mile north of Twelfth Street, and a southern route, requiring a similar diversion of more than 1 mile south. About thirty years ago, a steel viaduct for cable cars was built on Twelfth Street with a grade of about 13%, and car service was maintained until the present construction was commenced.

A roadway suitable for vehicular, as well as street-car, traffic on a viaduct to the top of the hill, on a viaduct to the bluffs, and in a tunnel emerging at some convenient point, and other such arrangements, have been advocated for many years, and have been made a feature of more than one political campaign, and of franchise negotiations with street-railway interests. The improvement finally realized as the Trafficway

extends from Liberty Street to Broadway, a distance of ¾ mile, of which the viaduct occupies about 2 300 ft. The remaining portion consists of earth embankments and cuts, with the usual street improvements on Twelfth Street, and the regrading of certain side streets to intersect its new grade. A street 60 ft. wide is thus provided on a continuous grade of about 5.5% for a distance of 3 500 ft., substantially from end to end of the improvement. It was physically impossible, without involving prohibitory expense and damage to existing structures, to extend the end of the grade in either direction, so the gradient practically fixed itself. To accommodate traffic desiring a less steep grade, and willing, for such advantage, to travel by a less direct route, a roadway on a lower deck is provided, with a grade of about 2.5 per cent. This lower roadway begins one block east of the upper one and extends to the bluff, a distance of 1 800 ft.; thus enabling all classes of traffic to avoid the grade crossings over the heavy service railway tracks on the street below. Ascending roadways or streets alongside the bluff from the end of the lower deck will terminate in streets at the summit of the hill, giving easy grades, although by indirect routes for team traffic bound up town. These connecting streets are not yet built.

Preliminary studies and estimates were made for viaducts of steel and of reinforced concrete; in the latter case, structures of arch spans, and also of girder spans, were considered. The city officials were favorable to the engineers' recommendations of concrete, and the girder type of structure was selected, the final general plan being as shown on Plate XVI. The suspended lower deck over Santa Fé Street, of the final plan, was developed instead of short spans with intermediate columns, to meet the desire of the railways for a clear span the full width of the street.

2.—General Description of Structure.

The Twelfth Street Trafficway Viaduct is a reinforced concrete structure consisting of girder spans supported by columns founded in part on rock, in part on soil, and in the main part on concrete piles. Over eight railway tracks in Santa Fé Street a long span is provided by the construction of an arch. The structure is about 2 300 ft. long, 60 ft. wide, and 120 ft. high at its highest point. The columns are in pairs transversely, and are placed so that the upper deck, which has a total width of 60 ft., cantilevers beyond the columns on each side, and

the lower deck roadway passes between them. The upper deck provides a roadway 30 ft. wide paved with creosoted blocks, a sidewalk 5 ft. wide, and a street-car space 22 ft. wide. The roadway is separated from the street-car space by a concrete curb, and on each side of the structure there is a concrete hand-rail. The two street-car tracks are built with the usual wooden cross-ties set in ballast, so that no other traffic can use the area which they occupy. This arrangement, somewhat uneconomical from a highway standpoint, was specified by the city authorities. Iron trolley poles on each side of the street-car space support the usual overhead trolleys. Stairways are provided at Hickory and Mulberry Streets to give access for pedestrians to the roadway from the ground surface. The lower deck, beginning at Hickory Street and ending at Beardsley Street, provides a single roadway, 30 ft. wide, paved with creosoted blocks. The longitudinal girders supporting this deck extend far enough above the roadway to form side barriers.

The upper deck comprises forty-five deck-girder spans of two girders each, varying in length from 33 to about 56 ft., the arch span, and two earth-filled approaches. The lower deck comprises twenty-seven through-girder spans of two girders each, supported on the same columns that carry the upper deck, the suspended deck of the arch span, and the earth-filled approaches. The floor-slabs are supported on cross-girders and cantilever beams. For the crossings of both decks over the streets, near the west end, very shallow floors are necessary, and concrete-encased steel beams in the floors, and concrete-covered steel girders, are used instead of the ordinary reinforcement. Both upper and lower roadways are lighted with incandescent electric lights, placed above the hand-rail for the upper deck, and on brackets on columns for the lower deck.

Below the structure Twelfth Street is about level from Santa Fé Street to the hillside, and gives access to Bluff Street leading northward along the bottom of the bluff. The space transversely between columns at the street level is 30 ft. Near the bluff, passing under the lower deck, the Kansas City Terminal Railway Company has two tracks carried by a concrete girder span above the ground surface of Twelfth Street, making four traffic levels at this point. Higher up on the hillside, just in front of the east abutment, the Kersey Coates Drive of the Park System passes below the upper-deck level.

Twelfth Street from Broadway to Santa Fé Street is 60 ft. wide, but for the three blocks, from Santa Fé Street to Liberty Street, it is only 30 ft. wide. Eleventh Street for these three blocks is 60 ft. wide, and the blocks between Twelfth Street and Eleventh Street are only 40 ft. wide. By securing these three very narrow blocks of property, a single street, 130 ft. wide for a distance of three blocks, was obtained, and the viaduct was placed about midway between, affording an excellent approach and retaining both Twelfth Street and Eleventh Street. This caused a shift in the alignment of about 30 ft., made by two easy curves at Santa Fé Street.

Careful attention was given to the architectural treatment in an effort to secure something more than a plain series of posts and beams. The treatment developed considers the columns as columns with plinths and capitals, and not merely as posts. The bottoms of the upper-deck girders are curved to give an arched or high cambered appearance. The lower-deck girders are straight and in effect are supported by secondary pilasters set out from the main columns. Certain limiting conditions of the railway and street locations crossing under the structure practically determined certain column locations, but the span lengths were made smaller near the lower end of the structure, affording uniformity of appearance and preserving the unity of effect, in spite of the great variation in height of the different columns.

The large arch at Santa Fé Street provides a central feature for the structure and was thus developed. The piers of the arch are carried up to the upper roadway and there support, on cantilevers, bays projecting beyond the usual hand-rail line. The capitals, plinths, mouldings, the projecting panels of the columns, and such features, are bold and heavy, without excess of fine lines, in keeping with the general dimensions of the structure. The architectural appearance has been favorably commented on, and it is believed effects a satisfactory solution of a rather difficult problem of a straight-line structure to be built with all possible economy and without any extra funds for adornment.

3.—Loadings, Specifications for, and Methods of, Design.

Assumed Live Loads.—The following loadings were assumed for design:

1.—For Slabs and Floor Systems:

On street-car tracks, Class 25, consisting of two coupled cars, each 52 ft. long and each weighing 50 tons, with impact allowance loads consisting of percentages of the preceding static loads, determined by the formula,

$$I = \frac{200}{L + 270},$$

where L is the length of track loaded;

On roadways, Class A, with an added impact allowance percentage determined by the formula,

$$I = \frac{100}{L + 150},$$

which, in total, consists of a load varying from 147 lb. per sq. ft., for a loaded length of 100 ft., to 200 lb. per sq. ft.;

On the sidewalk, Class B and impact, a corresponding loading varying from 123 to 167 lb. per sq. ft.

2.—For Girders and Arch Ribs:

On street-car tracks, Class 20, consisting of two coupled 40-ton cars, with impact percentage added;

On the roadways, Class B with impact;

On the sidewalk, Class C with impact, consisting of a load varying from 98 to 134 lb. per sq. ft.

The roadways were also considered to carry a 15-ton road roller, but without impact.

The wind loads figured were 30 lb. per sq. ft. of exposed surface for the unloaded structure, and 15 lb. per sq. ft. of exposed surface for the loaded structure. When considering maximum combined conditions of wind and temperature stresses, the allowable stresses were increased 30%, or as described later.

Allowed Unit Stresses.—For these assumed loadings, the following unit stresses were allowed in the design:

"For steel in tension, 15 000 lb. per sq. in.; for concrete in bending compression, 600 lb. per sq. in., tension zero; for concrete in direct compression, 450 lb. per sq. in., with not more than 400 lb. per sq. in. under expansion plates; for concrete in direct shear, 150 lb. per sq. in.; for concrete in diagonal tension, 35 lb. per sq. in.; for concrete in diagonal tension with part of steel bent up, 50 lb. per sq. in.; for concrete in diagonal tension with full shear reinforcement, 100 lb. per sq. in.; adhesion between concrete and deformed bar, 100 lb. per sq. in."

Designing Rules.—Some of the general rules for proportioning were:

"Column reinforcement shall have hoops spaced not farther apart than fifteen diameters of the vertical bars. The vertical steel shall be not less than 0.8%, nor more than 2.0%, of the minimum section of the column. The ratio of moduli of elasticity shall be taken as 15. The span length shall be taken as the distance from center to center of supports, but not to exceed the clear openings plus the depth of the slab or beam. The width of T-beams shall be considered to be not more than one-fourth of the span. Tension bars shall be spaced apart not less than three diameters of the bar, nor more than the thickness of the slab. If bond stress exceeds 100 lb. per sq. in., the ends of the bars shall be bent into a hook. The distance of the center line of bars to the surface of the concrete shall be not less than 1.3 d plus 0.17 in.; or, say, $\frac{3}{4}$ in. for $\frac{3}{8}$-in. bars, 1 in. for $\frac{1}{2}$ and $\frac{5}{8}$-in. bars, $1\frac{1}{2}$ in. for $\frac{7}{8}$ and 1-in. bars, and $1\frac{3}{4}$ in. for $1\frac{1}{8}$ and $1\frac{1}{4}$-in. bars. When stirrups are bent around the bars, allow an extra distance equal to the thickness of the stirrup, when the above distance is 1 in. or less, and equal to one-half the thickness when the above distance is more than 1 inch."

Controlling Conditions and General Methods.—The necessities of the surface street under the structure, from Santa Fé Street east to the bluff, required a transverse spacing of columns which placed one column almost midway under the street-car tracks and the other under the roadway. Thus, the columns, girders, and other parts of one side of the viaduct are much larger and heavier than those of the other side.

All parts of the structure, which could be so constructed, are designed for continuous action. The upper girders were figured as continuous beams for the various combinations of span lengths, assuming a uniform moment of inertia, a condition substantially existing; and the various sections of the girders were proportioned for the figured moments. The lower-deck girders were considered as beams restrained at their ends; the end sections were proportioned for the moment of truly fixed beams, and the center sections for a moment 10% in excess of the actual figured moment for the same condition.

The cross-girders and cantilevers of the upper deck were designed for the usual continuous conditions existing, and the lower-deck cross-girders as simple beams between the supporting girders. Considering longitudinal girders alone, it is easily apparent that the great number of spans of different length, and the varying combinations and num-

bers of spans between expansion points, required rather voluminous calculations for design. It may be of interest to state that the calculations for this structure cover about 300 closely-written, 10 by 16-in. sheets.

Two features of special interest, developed in the design, are the investigation of the columns and the calculation of the arch span at Santa Fé Street.

A.—Investigation of Columns.

The great height of part of the structure and the omission of all diagonal bracing in vertical planes, either transversely or longitudinally, made necessary a thorough investigation of the stresses due not only to every combination of live loads, to wind loads, and to changes in temperature, but especially to the secondary stresses from these loads, due to the rigid connections between the columns and the upper-deck and lower-deck cross-beams and longitudinal girders. It was clearly unnecessary to go to the extreme of attempting to design every separate column by calculating its every possible stress; so that a typical series of columns fairly representing the average was selected, and calculations, as nearly complete as might be, were made for them, in order to ascertain the maximum unit stresses that could be allowed for the direct loads as a simplified basis for column design, which would give results satisfactorily accurate. The essential features of this development are here presented in abbreviated form.

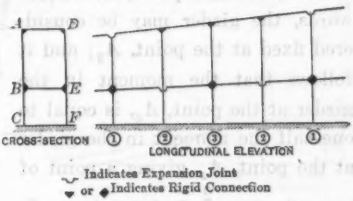

FIG. 1.

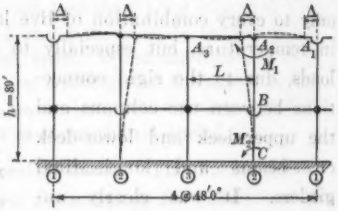
Fig. 1 shows a typical longitudinal section and cross-section of the viaduct. It will be noted that expansion joints are placed at every other column for the lower deck, thus eliminating all temperature stresses in columns, due to the shortening or lengthening of the lower deck. The upper deck has expansion joints generally at every fourth column, these joints staggering with those of the lower deck; all expansion joints for both decks are what may be called "double" expansion joints, the girders on both sides of the column being on sliding plates. The columns numbered (2) are, therefore, the only ones which have

stresses due to temperature changes. A complete investigation of this bent, therefore, was carried through.

To simplify the calculations, it will be assumed that all bents are of equal height and that the dimensions are as shown on Fig. 2.

Under the influence of a fall in temperature, the tops of Columns 2 will move toward the top of Column 3 equal distances, which are called Δ. Assuming that the lower-deck girders rest on frictionless rollers at the points, B, Columns 2 will deflect as if the lower deck were omitted.

Consider the upper girder between Columns 2 and 3; the deflection of Column 2 produces a moment, which will be called M_1, at the point, A_2. As the structure is symmetrical about the point, A_3, the tangent to the deflection curve will remain horizontal at that point, or, in other words, the girder may be considered fixed at the point, A_3; and it follows that the moment in the girder at the point, A_3, is equal to one-half the moment in the girder at the point, A_2, giving a point of contraflexure, $\frac{2}{3}L$, from A_2.



Indicates Expansion Joint
or ◆ Indicates Rigid Connection

FIG. 2.

It will simplify matters to substitute for Girder $A_3\ A_2$, a girder which is rigidly connected to the column at A_2 and is freely supported on an expansion bearing at the other end; the length of girder must be such as to give the same moment, M_1, at Column 2. This length will be $\frac{3}{4}L$. It is somewhat more simple to work with a girder length equal to L, so it will be assumed that the girder has a length, L, and that its moment of inertia, I, is increased to $\frac{4}{3}I$.

Evidently, the moments in the column will be unchanged if, for the two girders connecting to the column at A_2, one girder is substituted having a moment of inertia equal to their sum; the moment of inertia of this one girder will be taken, therefore, as $\frac{4}{3}I + I = \frac{7}{3}I$, where I is the moment of inertia of the actual girder.

As the columns are battered from top to bottom on all faces, there is a considerable variation in moment of inertia throughout their

lengths. Any formulas that are applied for the solution of the desired moments, M_1 and M_2, must take into account this variation in moment of inertia of the column. Consider the column and attached girder as a beam on three supports having moments, M_0, M_1, and M_2, at the three supports and having a straight-line moment variation, as indicated in Fig. 3; the beam is assumed to be fixed at C.

Fig. 4 shows the beam as deflected by the moments.

Bearing in mind that the deflection of any point, as A_1, with respect to a tangent at A_2, is equal to the moment about A_1 of the area under the $\frac{M}{E\,I}$ curve, we can write the following equations:

$$\delta_1 = \int \frac{M\,x\,d\,x}{E\,I}.$$

But, $M = \frac{M_1\,x}{L}$, and I is constant for this span, therefore, we have

$$\delta_1 = \frac{M_1\,L^2}{3\,E\,I} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

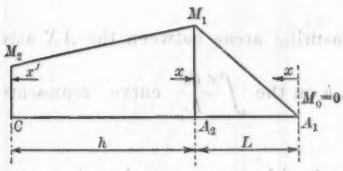


FIG. 3.

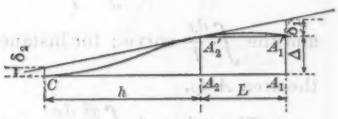

FIG. 4.

similarly, $$\delta_2 = \frac{M_2}{E}\int \frac{x'\,dx'}{I} + \frac{M_1}{E\,h}\int \frac{x'^2\,dx'}{I} - \frac{M^2}{E\,h}\int \frac{{x'_1}^2\,dx'}{I} \quad \ldots (2)$$

We have also the relation, $$\frac{\delta_1}{L} = \frac{\Delta - \delta_2}{h} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

We can eliminate the unknown quantities, δ_1 and δ_2 from Equations (1), (2), and (3), and have the following resulting equation:

$$\frac{M_1}{E}\left(\frac{L}{3\,E\,I} + \frac{1}{h^2}\int \frac{x'^2\,dx'}{I}\right) + \frac{M^2}{E}\left(\frac{1}{h}\int \frac{x'\,dx'}{I} - \frac{1}{h^2}\int \frac{x'^2\,dx'}{I}\right) = \frac{\Delta}{h} \quad \ldots (4)$$

A second equation involving only the unknown M_1 and M_2 can be written by considering the deflection of A_2 with respect to the tangent at C, as follows:

$$\frac{M_1}{E}\left(\frac{1}{h}\int \frac{x\,dx}{I} - \frac{1}{h^2}\int \frac{x^2\,dx}{I}\right) + \frac{M_2}{E}\left(\frac{1}{h^2}\int \frac{x^2\,dx}{I}\right) = \frac{\Delta}{h} \quad \ldots (5)$$

Numerical substitution in Equations (4) and (5) results readily in a solution of values of M_1 and M_2, the desired moments.

It might be of interest to explain the method used in ascertaining the values of the integrals, $\int \frac{x\,dx}{I}$, $\int \frac{x^2\,dx}{I}$, etc.

These integrals are plotted to scale on Fig. 5. The process of plotting is as follows:

1. Plot values of I, b represents the bottom of the girder—the deformation between A_2 and b was neglected, that is, I was assumed to be infinite.

2. Pl t values of $\frac{1}{I}$.

3. Plot values of $\int \frac{dx}{I}$; to locate a point of the $\int \frac{dx}{I}$ curve, measure the area between the $\frac{1}{I}$ curve, the line, $A\,C$, and the ordinate at the point; for instance, f on the $\int \frac{dx}{I}$ curve represents the area, $bcde$.

4. Plot values of $\int \frac{x\,dx}{I}$ by measuring areas between the AX axis and the $\int \frac{dx}{I}$ curve; for instance, h on the $\int \frac{x\,dx}{I}$ curve represents the area $Abfg$.

5. The value of $\int \frac{x^2\,dx}{I}$ was obtained by measuring the whole area between the $\int \frac{x\,dx}{I}$ curve and the AX axis.

The differential areas are shown on Fig. 5 and make clear, without further explanation, the correctness of these methods.

Stresses Due to Wind Loads.—In calculating these stresses, we have a 2-story framed bent to consider; the fact that the columns have a variable moment of inertia complicates the problem, and it is necessary to use formulas taking this into account. Further complication results from the fact that the two columns in the bent are unlike, with different elastic properties.

To solve the problem and ascertain the desired moments in the columns and cross-girders, the theorem of three moments is applied.

The bent under consideration is shown in Figs. 6 and 7.

Under the influence of the wind loads, H_1 and H_2, the frame will deflect in some such manner as that shown in Fig. 7. In this diagram

also are shown the unknown moments, M_0 to M_7, for which we must solve.

The 2-story frame, shown in Fig. 7, can be broken up into two separate frames, *ABED* and *BCFE*; in the consideration of the upper frame, *ABED*, M_2 and M_3 must be considered as external moments acting at *B* and *E*; similarly, for the lower frame, M_5 and M_4 are the external moments. Using the formulas for continuous beams, we can now write four equations for each frame, or a total of eight equations. We have ten unknowns in these eight equations, the moments, M_0 to M_7, and the deflections, δ_1 and δ_2. The two additional equations neces-

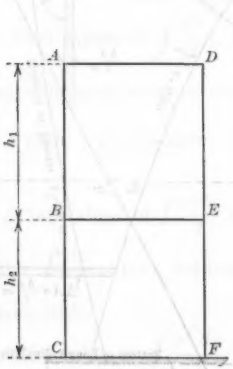

FIG. 6.

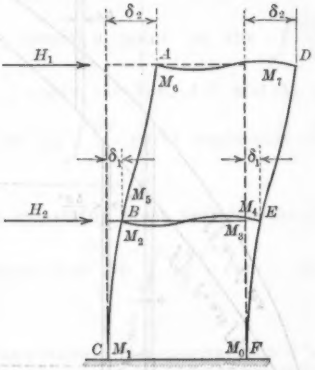

FIG. 7.

sary to solve can be obtained from the static equilibrium conditions, as follows:

$$H_1 h_1 = M_4 + M_5 + M_6 + M_7$$
$$(H_1 + H_2)h_2 = M_0 + M_1 + M_2 + M_3.$$

By arranging these ten equations in tabular form, the solution is found with comparatively little labor.

Unit Stresses in Columns.—The methods indicated for the calculation of temperature and wind stresses were in general used to evaluate the column bending stresses due to dead and live loads on the main girders and cross-girders. The columns are battered ⅛ in. per ft. on all four faces, and pilasters are added below the lower-deck girders; the result is that the maximum unit stresses in the columns occur at their tops, on a line with the bottom of the longitudinal girders. Various probable combinations of loading were considered; the maxi-

mum probable stresses that would ever occur in the columns were assumed to be covered by the following two cases:

Case A.—Live load in position to produce maximum reaction on column; transverse wind at 15 lb. per sq. ft.; temperature change of 40° Fahr.

Case B.—Live load on upper deck in position to produce maximum bending in a longitudinal direction; live load on lower deck in position to produce maximum reaction on column; transverse wind at 15 lb. per sq. ft.; temperature change of 40° Fahr.

The stresses for these two cases for a typical column were:

Case A:	Direct	355 *C*	355 *C*
	Wind	136 *C* or	136 *T*
	Rigid cross-girder connection.	86 *C* or	86 *T*
	Temperature	97 *C* or	97 *T*
		674 *C* or	36 *C*
Case B:	Direct	300 *C*	300 *C*
	Wind	116 *C* or	116 *T*
	Rigid cross-girder connection.	86 *C* or	86 *T*
	Temperature	97 *C* or	97 *T*
	Longitudinal girder connection.	182 *C* or	182 *T*
		781 *C* or	181 *T*

These stresses were figured on the basis of a plain concrete column, the reinforcement being neglected, and, considering the extreme conditions of loading, were thought to be satisfactory.

As a result of these investigations, the sections of the columns were determined on the following basis:

The column section under the cap was determined by providing for the maximum direct load on the column at 350 lb. per sq. in., steel reinforcement not being considered. The section above the column cap was made not less than 92% of the section under the cap. The columns were reinforced with 1¼-in. round bars, spaced at approximately equal distance around the perimeter of the column, so as to give a percentage of 0.8 of 1% at the point of minimum section on the heavy column of any bent. The steel for the light columns was then determined by using the same spacing as for the heavy column.

B.—Design of Arch.

Other designing problems of special interest are in connection with the arch at Santa Fé Street. This span has a clear opening of 130 ft., and consists of two arch ribs transversely spaced so that the lower roadway passes between them.

The two arch ribs support spandrel columns which, in turn, carry cross-girders of the usual type and the cantilevers of the upper deck. The lower deck is suspended from the arch ribs. Because of the very limited distance between the surface of the roadway on the lower deck and the clearance required above the railroad tracks below, the lower deck is composed of steel I-beams encased in, and carrying a slab of, concrete. These cross-beams rivet into continuous longitudinal steel beams which are supported at intervals of 17 ft. by hangers composed of two steel channels.

The horizontal thrusts of the arches are taken by the bottom chords of the steel eye-bars. This avoids the use of abutments large enough to resist the thrust—there being in fact insufficient room for such abutments—and affords several advantages because of the resulting ability to shorten the lower chords. Because of the short length of the hangers near the springing points of the arch, and the rigidity of the lower-deck girder, it was considered advisable to make the arches of the fixed type. One end of each arch rib is fixed by being built into the supporting pier, and the other end rests on a tandem rocker bent placed so as to keep the resultant thrust of the arch between the two bearings for every condition of loading. The springing points of the arch are relatively on the same grade as the lower roadway, so that the east springing point is 3.5 ft. higher than the west one. This condition causes some unusual longitudinal thrusts.

All the structural steel members of the span are encased in concrete, and the smaller ones are surrounded by light concrete walls giving dimensions for satisfactory architectural appearance.

The arches were designed under the usual elastic theory. The calculations were carried through for both unit vertical and unit horizontal loads at the various points, vertical loads in this instance meaning those perpendicular to, and horizontal loads meaning those parallel to, the arch axis. These latter loads include those due to thrust from the street-car loading, as well as the components of the dead and live loads caused by the grade.

The maximum stresses were calculated at each springing point, at the crown, and at seven intermediate points on each half of the ring—a total of seventeen different points. All calculations were carried through in appropriate tabular form, and are hardly of sufficient interest to warrant their inclusion in this paper. The influence lines for maximum moments at various points, due both to vertical and to horizontal loads, were plotted and are shown on Plate XVII.

Considerable experience in actual designs recommends highly the influence-line methods for a check on calculations. Errors seem to be invariably made evident by the failure of the various ordinates to any influence line to show a smooth curve. In the diagrams, it will also be noted that the apices of the various moment curves themselves lie on a smooth curve, a further check on the numerical work.

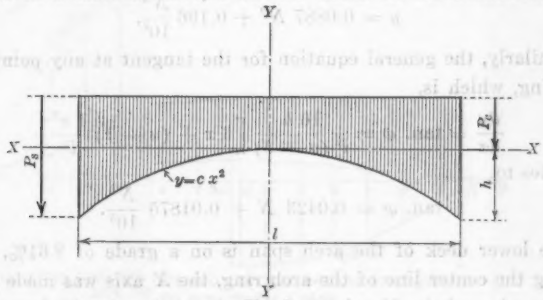

FIG. 8.

It was assumed that the intensity of loading on the arch ring, including the weight of the ring itself, would vary as the ordinates of a parabola, a condition of loading shown by Fig. 8; and the center line of the arch ring was located in the following manner:

Let P_c = equivalent uniform load at the crown;

P_s = equivalent uniform load at the springing;

$$u = \frac{P_s}{P_c};$$

h = rise of arch ring = 24 ft.;

l = span of arch ring = 134 ft.

Then, the equation of the funicular polygon results as follows:

$$y = \frac{4\,h}{l^2\,(u+5)}\left[6\,x^2 + (u-1)\,\frac{4\,x^4}{l^2}\right].$$

This equation was used as the equation for the center line of the arch ring, using dead load plus one-half live load in substituting

the numerical values of P_c and P_s. This substitution gave slightly different values of u for the two arch rings; and therefore an average value of $u = 1.34$ was used.

The equation was further simplified for use by dividing each half of the arch ring into sixteen equal horizontal sections, and numbering the division points successively from the crown to the springing.

Let N = number of any division point;
= 0 at crown;
= 16 at springing;

Then, $X = \frac{N\,l}{32}$.

Substituting the values of u, h, l, and x in the original equation, we have the following equation for the center line of the arch ring:

$$y = 0.0887\ N^2 + 0.196\ \frac{N^4}{10^4}.$$

Similarly, the general equation for the tangent at any point of the arch ring, which is,

$$\frac{dy}{dx} = \text{tan. } \phi = \frac{16\ h}{l^2\ (u + 5)} \left[3\ x + (u - 1)\ \frac{4\ x^3}{l^2}\right]$$

simplifies to,

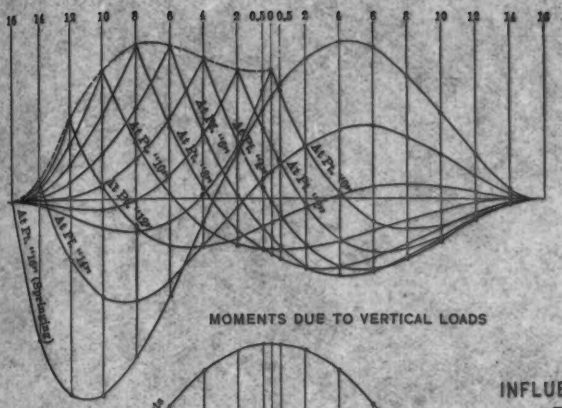
$$\text{tan. } \phi = 0.0423\ N + 0.01875\ \frac{N^3}{10^3}.$$

The lower deck of the arch span is on a grade of 2.61%, and in locating the center line of the arch ring, the X axis was made parallel to the grade and the Y axis perpendicular to it. As the hangers supporting the lower deck are vertical, it is evident that the dead loads are not applied symmetrically with respect to the crown of the arch ring. For purposes of calculation, it was assumed that the loads were applied symmetrically; this resulted in an error of less than 1%, which was considered negligible.

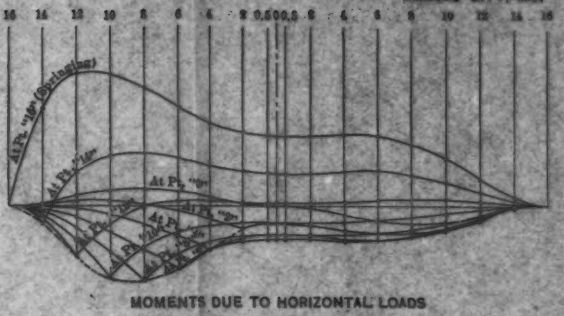
The use of the bottom chords of the eye-bars to take the thrust eliminates all temperature stresses in the arch rings, with the exception of those due to a possible variation in temperature between the arch ring and the bottom chord, which were considered negligible.

Toggle arrangements to shorten the lower chords were provided to accomplish the following:

1.—To take up the stretch in the bottom-chord eye-bars, due to dead load, the result being to leave the dead-load stresses in the arches the same as for fixed arches supported on rigid abutments.

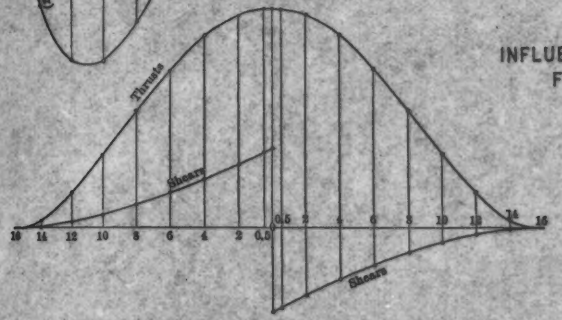


MOMENTS DUE TO VERTICAL LOADS



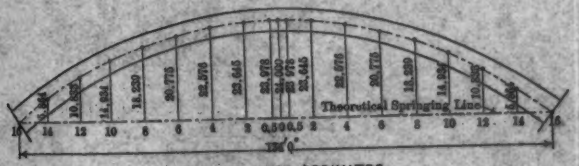
MOMENTS DUE TO HORIZONTAL LOADS

INFLUENCE LINE DIAGRAMS FOR ARCH SPAN



HORIZONTAL THRUSTS AND VERTICAL SHEARS AT CROWN DUE TO VERTICAL LOADS

HORIZONTAL THRUSTS AND VERTICAL SHEARS AT CROWN DUE TO HORIZONTAL LOADS



ARCH RIB WITH ORDINATES

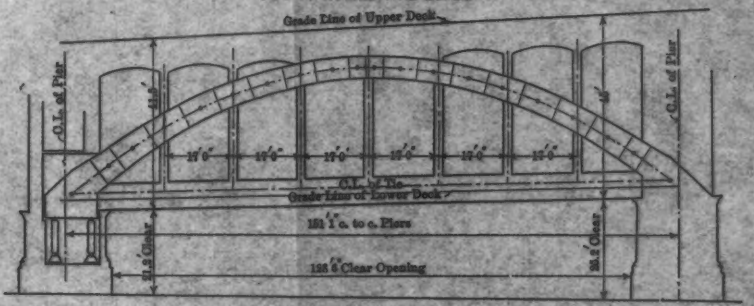


DIAGRAM OF GENERAL DIMENSIONS OF ARCH SHOWING ASSUMED DIVISIONS OF ARCH RIBS

2.—To shorten the bottom chords by amounts sufficient to eliminate the stresses in the arch rings due to their shortening under dead load.

3.—To shorten the bottom chords by the amounts which they would stretch, and the arch ribs would shorten, under full live load, over one-half the span.

As indicated by the influence lines for maximum moments at various points of the arch ring, the loaded length for a maximum moment is generally about one-half the span length; the result of shortening the bottom chord as indicated under Paragraph 3 is, therefore, to give practically the same maximum stresses in the arch ring as would result in a fixed arch supported on abutments in the ordinary way, with the further advantage that the stresses due to rib shortening are eliminated.

All these provisions required a total shortening of the bottom chords by the toggles of $1\frac{1}{16}$ in., which meant that the distance between the springing points, after the dead load was placed on the arches, was $\frac{3}{4}$ in. shorter than when the arches were constructed on the falsework.

4.—Specifications for Materials and Workmanship.

The specifications were prepared with a view to letting a unit-price contract after competitive bidding. Every effort was made to have them full and precise in description, both of materials and of workmanship, eliminating as far as possible the uncertain characterization of work "satisfactory to the Engineer" by expressing, wherever feasible, the views of the engineers in advance, and attempting to make perfectly clear to a prospective builder just what would be required of him. Though definite and explicit in the description of results desired, the specifications left open as far as possible the methods by which such results were to be secured, in order that the City might receive the full benefit of any contractor's skill and ingenuity in laying out and handling the work, and enjoy a portion of the economies thus effected.

Approximate quantities of various units of the structure were prepared and tabulated by the engineers. The City received bids on a unit basis of price per cubic yard for concrete in various divisions of the structure, price per pound for reinforcing material, for structural steel, etc., and the total bids were compared on the basis of the approximate quantities.

Concrete.—The specifications required the concrete of the structure to be made of 1 part cement, of detailed requirements, conforming in most respects to the recommendations of the American Society for Testing Materials; of 2 parts sand, "particles of hard, clean stone in graded sizes which shall pass a sieve having holes ¼ in. square, and not less than 50% be retained on a No. 30 sieve"; and 4 parts broken stone, "pieces of hard and durable rock entirely free from clay, loam, or any other material than sound, hard stone—of crusher-run sizes—with all material that will pass a ¼-in. sieve removed", to pass a 1½-in. ring.

For the hand-rails, stair risers, and treads, a proportion of 1 part cement, 1½ parts sand, and 3 parts broken stone, to pass a ¾-in. ring, was required. The proportions are stated to be by volume, with the ingredients measured loose, one 380-lb. bbl. of cement being taken as 4 cu. ft. The upper ¾ in. of the sidewalk slab is of mortar of 1 part cement to 1½ parts sand placed before the supporting slab had set. The use of a mechanical batch mixer is specified, to be operated long enough after the last ingredient is deposited in it thoroughly to mix and incorporate all ingredients.

Reinforcement.—The reinforcement is of corrugated bars, "deformed bars having their corrugations at right angles to the length of the bar" having been required, rolled from open-hearth billets of medium steel having an ultimate strength of from 60 000 to 75 000 lb., and a minimum elastic limit of 35 000 lb., and affording an elongation of not less than 22% in 8 in.

The specifications provide that the "reinforcement in the finished structure shall conform accurately in size and position to the requirements of the plans. Bars shall be firmly bound and tied together by wire where they lap or cross, or be fastened by clips or other devices. Each piece must be held rigidly and positively in position, so that there will be no displacement during the depositing of concrete".

Concrete Piles.—Precast reinforced concrete piles were designed, and were detailed on the drawings, but the specifications left some option to the contractor as to the exact type to be used, excluding, however, "piles in which fresh or unset concrete is placed against the soil". The contractor finally elected to use Raymond piles, which were accepted by the engineers.

A description of this well-known concrete pile is hardly necessary, but it may be said briefly to consist of a sheet-steel shell, spirally

reinforced, driven into the ground on a collapsible steel core. After reaching a satisfactorily resisting penetration, the core is withdrawn and the shell is filled with concrete. No reinforcing rods in the concrete were required, and as the concrete was not to be disturbed after placing, a mixture 1 part cement, 3 parts sand, and 5 parts broken stone was permitted.

Pavement.—The specifications for the creosoted wood block pavement for the lower roadway and on the street contain no unusual features. For steeper grades the following requirements are of interest:

"Creosoted block pavements, for roadways having a gradient exceeding 4%, are to be constructed in all parts of material and as specified for level roadways with the following exceptions: Creosoted laths about 1½ in. wide, ⅜ in. thick, and 4 ft. long, surfaced on one side, of uniform thickness, are to be furnished and placed on edge between every row of blocks continuously across the roadway, leaving a space about ⅜ in. wide and 2¾ in. deep between every row of blocks. The spaces between the blocks shall be filled with hot gravel which has passed through a sieve having holes ¼ in. square, and from which all sand and fine material which will pass a No. 20 sieve has been removed." * * * "Immediately after the gravel is in place, before it has cooled, paving pitch, as herein specified, shall be poured into it in such manner and quantity as entirely to fill all interstices."

This is practically the form of block pavement used in Vancouver, B. C., and elsewhere, on heavy grades. It affords a good grip for horses, and has proved very satisfactory.

Water-proofing.—The surfaces of both decks are covered with water-proofing in an effort to prevent the dripping of water on the roadways below. Under the ballast of the street-car area, this water-proofing consists of a two-ply burlap mat, laid down in water-proofing pitch, on which is placed a layer of asphaltic felt, and this, in turn, is covered with 1 in. of asphaltic mastic, and given a sand finish. Under the creosoted block pavement, one layer of burlap and one layer of asphaltic felt are laid in water-proofing pitch and given a sand finish. Indentations are formed in the concrete curbs some 6 in. below their tops, and the water-proofing mats are brought up, turned in, and finished in them. It happened that just before the contractor was to place his order for the burlap, the supply was entirely cut off owing to the European war conditions, so that felt was substituted, at some reduction of cost.

Lighting System.—The requirements for the lighting system were given as follows:

"The structure is to be illuminated by an electric lighting system. There shall be furnished and installed, all lamps, globes, conduits, wiring, and all other apparatus and appurtenances necessary for a complete series-Tungsten lighting system, taking current from the Kansas City Electric Light Company's 6.6-ampere, constant-current feeders at the east end of the structure. There will be two circuits. The circuit for lighting the upper roadway will have sixty 125-watt, 6.6-ampere, constant-current series-Tungsten lamps. Each lamp will be supported on a cast-iron standard, and will be surrounded by an opal glass globe, 14 in. in diameter. The circuit for lighting the lower roadway and the stairways will have fifty-six 75-watt, 6.6-ampere, constant-current, series-Tungsten lamps. Each lamp will be supported on a cast-iron standard or bracket, and will be surrounded by an opal glass globe, 12 in. in diameter. All wiring shall be drawn into Sherardized steel-pipe conduits of a satisfactory type, so as to be free from all flaws or mechanical injuries. All wires shall be No. 6, high-tension, lead-covered, Okonite, stranded, copper wire of the best quality. The conduit shall be encased in the concrete as the latter is placed, and shall be properly supported and arranged so that, later, the wire may be drawn into place. Suitable expansion joints shall be provided, and all connections shall be made in the conduits so that they will conform properly to the requirements of the structure. All joints between pipes and between pipes and boxes shall be made water-tight. The entire lighting system shall be constructed in a thoroughly workmanlike manner and to the satisfaction of the engineers."

Other features of the specifications will be evident from the descriptions of methods of construction.

5.—Equipment for, and Methods of, Construction.

Yard Space.—The contractor's plant was at the west or low end of the viaduct, where some storage space, switch tracks, sidings, and facilities for handling materials, were more easily available than elsewhere on the right of way. The working space comprised practically all the ground from Liberty Street to Hickory Street, and from the north curb line of Eleventh Street to the alley south of Twelfth Street, an area of about 35 000 sq. ft.

Three standard-gauge spur tracks were provided, one track paralleling Twelfth Street in the alley south of it—used for the delivery of timber—and two tracks crossing Twelfth Street at right angles—one for the delivery of sand, stone, and steel, and the other for cement.

Concrete Plant.—The mixing plant, placed on the line of the viaduct, consisted of elevated bins for sand and broken stone arranged to discharge into measuring hoppers, below which a 33-cu. ft. Chicago-cube mixer was installed. The mixer dumped the concrete into hopper cars operating on a 30-in. gauge track passing underneath. Stone and sand were delivered in bottom-dump cars and unloaded into a receiving pit alongside the bunkers. A 22-in. Jeffery, belt-bucket elevator, of a total height of 70 ft., raised the stone and the sand from the pit to the top of the bins, where a baffle-board directed each to a proper bin. One elevator thus handled both sand and stone, unloading first one and then the other. The cement was hauled up an inclined track from the cement storage shed on a car, self-dumping at the top, to a platform under the sand bin, where it was filled into a sheet-iron tube with a bottom gate, and so discharged into the mixer. The tube was of just the proper dimensions to hold six sacks of cement, the normal charge. The limited room for tracks made necessary considerable shifting of the cars, as only the first car of a train could be placed over the pit. The operations of unloading and mixing were not always simultaneous, but when all operations were going forward, there were required, severally, two men for unloading and handling the elevator, three men for unloading cement from cars, one in the storage shed, two opening sacks and feeding to the mixer, and one man attending to charging and operating the mixer. Thus, the services of nine men were needed for the unloading and mixing of concrete ingredients.

During severe weather, the stone, sand, and water for the concrete were heated by passing steam from a 60-h.p. boiler into the bottoms of the sand and stone bins, and into the water, thoroughly and satisfactorily heating all the materials.

Equipment for Steel and Timber Reinforcing.—The steel-storage yard was adjacent to one of the switch tracks, and was equipped with a working platform and a power bar-bender of ingenious design. This bender was devised on the job, and included a motor connected by a worm gear to a vertical shaft which had at its upper end a clutch with a jaw to engage the bars to be bent, thus bending the bars in a horizontal plane on a protractor plate to any desired angle. The lumber-storage yard was beside the third siding. From this lumber yard, the material was passed into a wood-saw shop, thence into the carpenter shops, and then forward to the structure. The wood shop was equipped

with a circular rip-saw, a "Hall and Brown rip-saw No. 131", a "Crescent" 36-in. band saw, a "Crescent" swing cut-off with 18-in. saw, and a universal edger and planer known as "Hall and Brown New Model Single Sticker No. 30".

There was also a well-equipped blacksmith shop.

Transportation.—All materials were put in form as nearly as possible ready for erection in this yard. All were conveyed out to place on a double narrow-gauge, industrial track carried on a tramway trestle some 8 ft. above the finished roadway surface, on the falsework, or on the partly finished structure. As construction proceeded, the tram tracks were placed on the upper roadway. The cars operating on this track were hauled forward and backward in pairs by a cable operating on two drums of a hoist placed on the mixing plant; the empty car being returned as the loaded car was hauled out.

For conveying concrete, four 2-yd., side, bottom-dump care were used; and about six sets of trucks provided cars of various lengths for handling forms, steel, etc. Two light traveling derricks of about 2 tons capacity, one on the lower deck and the other on the upper tramway on top of the upper deck, were each equipped with electric hoists.

The entire equipment, including elevators, concrete mixer, woodworking machinery, blacksmiths' tools, bar bender, etc., was operated by electricity, alternating-current, 220-volt, 3-phase, 25-cycle being available, and individual motors being attached to the various units.

Pile-Driving Equipment.—The piles were driven with a steel-frame, turn-table driver with 56-ft. steel leads, equipped with a 42-h.p. hoisting engine and a No. 1 Vulcan steam hammer weighing 5 tons, resting on rollers supported on wooden sills laid on the ground. Timber cribbing was used to support the sills across the excavations. There were, of course, the usual collapsible pile cores and other special equipment required in the construction of Raymond piles.

With the exception of the pile-driving outfit, practically the entire equipment was purchased new for this work and was carefully selected, in order to fit exactly the service needed. The orderly progress of the work is a testimonial of the adequacy and suitability of the plant.

Procedure of Sub-Surface Work.—The excavations, for the most part, were very simple, not very deep, on account of the concrete piles, and in a sandy loam, easily dug, and standing without much shoring

FIG. 11.—BACK VIEW OF MATERIAL BINS AND MIXING PLANT, SHOWING PIT AND BELT BUCKET ELEVATOR.

FIG. 12.—FRONT VIEW OF MATERIAL BINS AND MIXING PLANT, SHOWING MIXER, CONCRETE CAR, HOIST, ETC.

or sheeting. Near the east end of the viaduct there was considerable old, filled material; and rock was encountered at various elevations. The east abutment rests in part on clay and shale with front toe-walls, 5 ft. thick, carried to rock at about 10 ft. lower elevation. The work was simple, open excavation.

After excavations were made, the Raymond concrete piles were driven, in the usual manner, to the refusal the apparatus would stand. The engineers required that all the steel shells for a group of piles be driven and then the concrete for all be placed at one time. This was to prevent any possible damage to the unset concrete of one pile by the driving of another near it. No particular difficulty resulted, except that the shells would sometimes partly fill with water or with sand and silt, which had to be pumped out before depositing the concrete. The shells stood open without collapse, except where water-bearing, so-called "quicksand" was encountered, and there it was found necessary to fill each shell as driven. In the main, the concrete for the piles was mixed in the general mixing plant, but, in some instances, for convenience, small quantities were mixed by hand.

Forms and Falsework.—The forms and falsework merit special attention, for their construction, erection, and removal formed the principal items of labor cost of the whole structure, and the efficiency with which the work was carried forward was dependent in no small degree on the thoroughness and care the contractor used in their design and construction.

Plans and sketches were prepared dimensioning all special parts of all forms, and, as far as possible, controlling portions were constructed in the carpenter shops and taken out entire for erection; only the principal portion of the sheathing was put on in place in the usual manner. Though the structure has an effect of duplication, there is, in reality, very considerable variation of dimensions within small limits, so that there were few parts of forms removable and replaceable without alteration. For instance, there are no two columns of the entire structure alike.

The forms for the columns were built to dimensions in the carpenter shops in three principal parts; a ready-to-erect form for plinth and for capital, and partly finished forms for the shafts, comprising four side frames of correct height and batter, from 8 to 12 in. wide at each corner, or rather extending back to the raised panel of

The depth is measured in radial direction.

This detail typical for entire arch, except as noted

the column. The sheathing over the panels was prepared and placed after the side frames were adjusted to position. Yokes surrounding the column, of the usual four timbers bolted at the corners, and tied across with a central bolt surrounded by a tin tube, were placed at intervals and given bearing by wooden wedges.

For the upper-deck longitudinal girders, and the cross-girders between columns, which had curved bottoms, the forms were built in place by the usual building-construction methods. The curved joists under these girder forms were framed and bolted together full length, carried out, and placed entire; and short lagging boards, the length of the girder width, were nailed on. The side-lagging was placed longitudinally on 2 by 6-in. studding, placed in pairs at suitable intervals, and tied across by bolts. The lower bolts passed through below the bottom sheathing, and were not encased by the concrete.

The forms for the intermediate cross-beams were of the same general design, except that the sides were made of a series of panels about 2 ft. wide with a vertical stud at each side. After the bottom forms had been prepared, these panels were easily and rapidly set up alongside each other and supported by bolts passing across between the pairs of studs. The erection, removal, and re-erection of these panels was simple and easy; and their use effected considerable economies.

The cantilever beams on each side of the structure were also duplicated forms, and were built in two unit-sides ready to be placed on a bottom form and bolted together. The bottom joists were sawed to correct form in the shop and sheeted after being placed. The cracks between the sheeting on all these curved surfaces were filled, or pointed up, with clay just before placing the concrete.

The decking between beams and girders was supported on joists resting on string pieces fastened to the vertical studs of the beams and girders, as is customary in building construction. Forms for abutments and retaining walls were built in the usual fashion. Portions of the hand-rails, stairways, etc., were built of units cast in wooden forms generally lined with sheet steel.

The falsework supporting the lower-deck forms consisted of bents of posts under each cross-girder, braced together transversely and longitudinally. A short longitudinal cap was placed on each post with small diagonal braces. The bents were built complete with

bracing on the ground and set up with the derrick traveling on the lower deck. The posts were generally 6 by 6-in. timbers, supported on ordinary ground-sills, and the bracing was of 3 by 6-in. pieces bolted in place.

The falsework supporting the upper deck forms was of similar bents resting on the lower-deck floor-slabs, with the posts under the main girder supported on the main girders below. These were made in three parts; a central bent of three posts and bracing supporting the central portion of the cross-beam, and two side bents of three posts each with a cap cantilevered to each side, one end of the cap supporting the cantilever beam and the other extending far enough under the cross-beam to carry a corresponding load, balancing the entire cap load over the posts. These three parts of each bent were prepared on the lower deck near position, or were carted out to position on wagon trucks and raised by the derrick on the upper deck.

The requirements of horizontal clearance for the railroad tracks on Santa Fé Street made necessary the use of three pairs of small wooden truss spans to support the forms for the arch ribs. These trusses rested on bents of posts set in available spaces between the tracks. The arch centering was placed on top of them, and the lower deck forms were suspended from them.

Falsework and forms for about seven girder spans were provided and carried forward as it was removed, the posts of the falsework being spliced as the height increased.

Procedure.—The falsework, forms, and pouring were each, relatively, on the lower deck about two span lengths ahead of the upper deck, as the falsework for the upper deck could not be placed on the lower-deck concrete until it had hardened somewhat. The whole construction thus moved forward in sequence, maintaining about the same relation of lower deck advance. This sequence of operations is shown by Fig. 20.

The reinforcing bars were delivered, as far as possible, in lengths correct for use. Diagrams were prepared showing the shape and dimensions for bending each bar and assigning a mark to it. The bars were bent in the yard, and each special bar was tagged with its erection mark on a linen tag. Groups of plain bars, etc., were not tagged individually.

As the forms neared completion, the prepared bars were carried out on the tram cars and set in place. Metal clips, separators, and wire ties at the crossing of every two bars, supported them in place. Use was made of small cement briquettes or blocks in some cases to hold the bars up from the forms.

The placing of bars and depositing of concrete in the columns was carried forward in customary routine. For the upper deck, all the bars were placed for main girders, cross-girders, cantilevers, and slabs complete from the last division to a bulkhead placed across the structure at a convenient point. Concrete was poured continuously across the whole width of the structure, filling the girders, beams, slabs, etc., without a stop, for the longitudinal distance selected.

The concrete was transported in cars, as described, hauled by cable, discharged into a movable distribution hopper, and from this into Insley chutes, which conveyed it to final position in the forms. A trussed steel chute about 80 ft. long carried the concrete from the receiving hopper on the upper deck forward to position in the lower portions of the structure. The concrete was mixed to a soft consistency so that it flowed readily, but it was not so wet as to have water standing on its surface. It was spaded and sliced at the forms and around the reinforcing bars to insure complete contact, and to work forward the mortar.

The maximum capacity of the concrete plant delivering 1 300 ft.—or, say, to the mid-point of the structure—was about 30 cu. yd. per hour. The largest quantity placed in continuous run was about 450 cu. yd. in 15 hours. A trip one way, from the plant to the east abutment, required 3½ min.

The hand-rail units were cast on the deck in metal-lined wooden forms, near the place where they were to be used. The lower rail was cast in place, the separately cast balusters were set in it in rows, and the pre-cast top rail was set on them, extending into the posts. The forms for the posts, except for the capital, were clamped on, and the posts were cast in place. The stairs were cast in units of one riser and one tread. These were supported on falsework and projected into the forms for the supporting girders, which were built in place.

Materials and Wages, General Observations.—The total quantity of timber used on the job was about 1 500 000 ft. b.m. This may be

roughly divided into 600 000 ft. of form lumber, 850 000 ft. of falsework, and 50 000 ft. in general use, including bins and mixing plant. The average cost of this material was about $20 per thousand, or about $1 per yd. applied to the whole concrete, or $1.25 per yd. applied to concrete above the bases.

The number of men employed varied from 150 to about 325, an average of about 200 men, of whom, perhaps, 150 were carpenters and helpers. The wages prevailing were, for common labor, $2.00, for carpenters' helpers, $2.50, for carpenters, $3.50, for finishers, $3.50, and for derrick and hoist operators, $4.00; all for 9 hours per day.

The conduct and execution of the work merit special comment. The viaduct was built substantially in the allowed time of 15 months, moving forward in logical and orderly manner, largely due, of course, to systematic handling of labor and materials. On the first day of every week, a schedule of work to be accomplished each day of that week was prepared in writing, and the foremen were instructed, not only what to do each day, but also how much had to be done. If the amount assigned was not completed at the usual stopping time, the men kept at work until it was done. This applied particularly to placing concrete, the day's run being completed more than once after midnight. The conditions surrounding the work permitted it to be handled as a manufacturing proposition, and with factory-like precision and system.

There was some difficulty in securing stone as clean as desired, for the limestone strata in this region are overlaid with clay and other objectionable materials; and, especially during a rainy season, it is impossible to prevent some clay and soft shale from mingling with the stone in the crusher bins. In fact, the more careful crushers shut down during rainy weather to avoid this difficulty. The stone cost $1.15 per cu. yd., delivered in cars at the site. The sand supply from the Kaw River is clean, sharp, and well graded, testing about 52% retained on a No. 30 sieve. Its cost delivered in cars at the site was about 65 cents per cu. yd. The cement was Kansas City-Portland, manufactured in a mill about 15 miles from the site, and costing, delivered in cars at the site, $1.20 per bbl. (plus sack loss). These delivered prices include somewhat complex switching charges.

Reinforcing steel delivered cost about 1.75 cents per lb.

6.—Quantities and Costs.

The contract assigns unit prices for forty classified items, including many classifications of concrete with regard to location in the structure. The following summarized figures were prepared from such classifications, and an attempt has been made to give the salient features of the final quantities of the structure, as built. These costs are the amounts paid by the City, and include the contractor's profit.

There are about 32 500 cu. yd. of concrete, distributed about as follows:

	Cubic yards.
Concrete piles	1 360
Columns, piers at Santa Fé Street, and footings	11 300
Upper deck, including girders, cross-girders, cantilevers, floor-slabs, etc.	11 300
Lower deck, including girders, cross-girders, floor-slabs, etc.	3 600
Retaining walls and abutments	3 000
Ribs of arch at Santa Fé Street	600
Hand-rails	500
Stairways, sidewalks, curbs, paving base on fills, and miscellaneous	800

No special payment was made for excavation, but the amount paid for concrete included its cost. The total excavation was about 10 000 cu. yd. The amounts paid for concrete in place varied from about $8.00 to $13.50 per cu. yd. for different classifications, averaging $9.45 for the whole structure, omitting only the piles and the hand-rails, as both of these were paid for at linear foot prices.

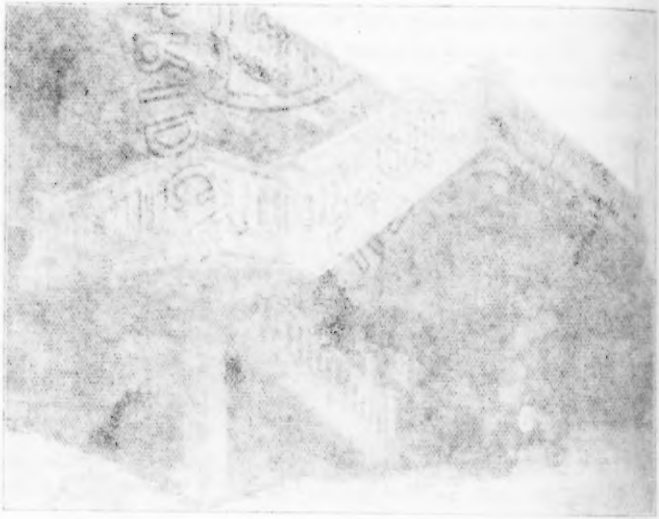
There were driven 2 610 piles, having a total length below bottoms of footings of about 47 000 lin. ft. and an average length each of 18 ft., costing in place $1.20 per lin. ft.

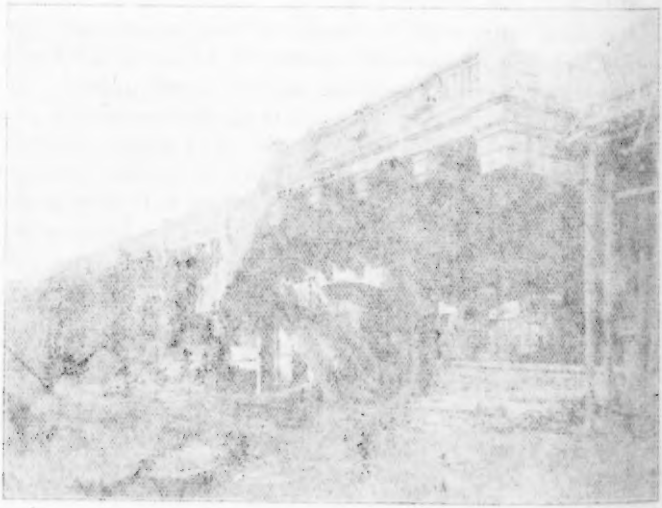
The approximate quantities of metal, and the prices paid for it in place are as follows:

Reinforcing steel, ¾ in. in diameter and greater	2 900 000 lb. at 2.95 cents per lb.
Reinforcing steel, less than ¾ in. in diameter	1 000 000 lb. at 3.25 cents per lb.
Unfabricated metal, such as bed and bearing plates, guard-angles, etc.	100 000 lb. at 4.40 cents per lb.
Fabricated structural metal	620 000 lb. at 4.60 cents per lb.
Cast-iron lamp-posts and brackets	25 000 lb. at 5 cents per lb.

FIG. 23.—STAIRWAY AT HICKORY STREET, TWELFTH STREET TRAFFICWAY VIADUCT.

FIG. 24.—STAIRWAY AT MULBERRY STREET, TWELFTH STREET TRAFFICWAY VIADUCT.





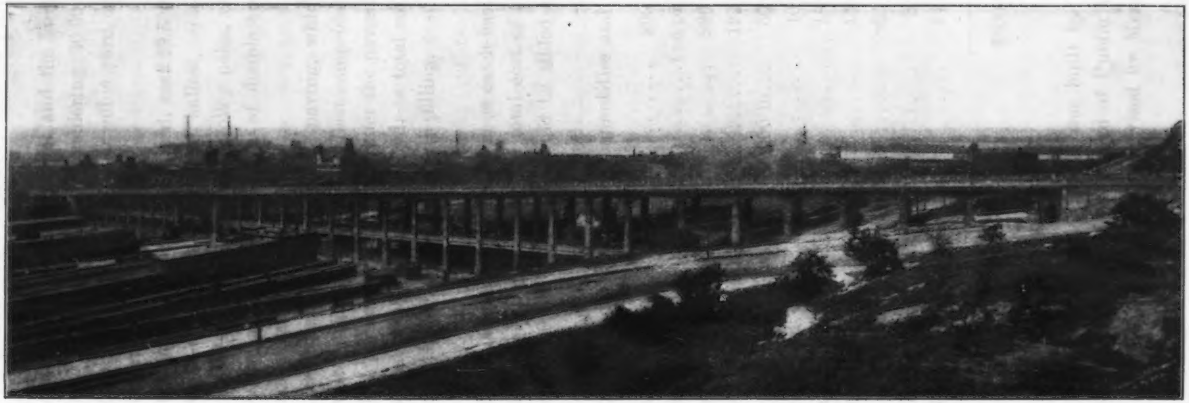


FIG. 25.—TWELFTH STREET TRAFFICWAY VIADUCT, KANSAS CITY, MO.

Omitting the fabricated structural metal and the lamp-posts gives a total of 4 000 000 lb. of metal, or, considering 30 600 cu. yd. of concrete, an average of 130 lb. of metal per cubic yard, at an average price of 3.06 cents per lb.

The lighting system, complete as described, cost $9 500.

The double street-car tracks, including ballast, cross-ties, track rails, inner steel guard-rails, bonding, and trolley poles, cost, in place, a total of $18 000 for a length of 2 600 ft. of double track, or, say, $3.50 per lin. ft. for single track.

There are 14 500 sq. yd. of wood-block paving, which cost $2.25 per sq. yd. The water-proofing under the ballast comprised about 5 000 sq. yd., costing $1.71 per sq. yd., and that under the pavement included 11 500 sq. yd. at a cost of 58.5 cents per sq. yd.—a total cost of $15 000.

There were some 40 000 cu. yd. of earth filling, costing 28 cents per cu. yd.

There were other miscellaneous items such as catch-basins, drainage pipes, sewer connections, etc., bringing the total cost of the structure to the city to about $600 000, to which should be added some $40 000 for engineering.

The following is a summarized table of quantities and costs:

Concrete piles (2 160)	$60 000
Excavation, about 10 000 cu. yd.	(no price)
Concrete, 30 600 cu. yd.	290 000
Reinforcing metal, 4 000 000 lb.	122 000
Structural metal and castings, 645 000 lb.	30 000
Lighting system	10 000
Street-car tracks, etc.	18 000
Water-proofing	15 000
Block pavement	33 000
Hand-rails	8 000
Earth filling and miscellaneous	14 000
	$600 000

7.—Personnel.

The Twelfth Street Trafficway Viaduct was built by the City of Kansas City, Mo., under control of the Board of Public Works. The plans were made and the construction supervised by Messrs. Waddell

and Harrington, Consulting Engineers, under the personal supervision of Mr. Harrington. The writer prepared the general preliminary studies and estimates, directed the design, and wrote the specifications. L. R. Ash, M. Am. Soc. C. E., was City Engineer at the time the plans were adopted, and after joining the firm, directed the construction work. The details of design were largely the work of Messrs. A. E. Slettum and C. W. Yelm. Mr. M. J. Maher was Resident Engineer, in charge of the entire construction work.

The structure was built under one general contract by The Graff Construction Company, of Seattle and Kansas City. Mr. Graff gave the work his constant personal attention, and was ably assisted by his superintendent, Mr. Harold E. Ketchum, in handling the building operations and in the design of the contractor's plant, falsework, forms, and other temporary structures; Mr. George Hockensmith was General Foreman.

For their courteous assistance in the preparation of these data, the writer desires to express his cordial appreciation to the above gentlemen and to H. C. Tammen, Assoc. M. Am. Soc. C. E., at present Designing Engineer of Harrington, Howard, and Ash.

DISCUSSION

F. W. GREEN,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has made a noteworthy contribution to engineering literature. Unique seems to be the word best adapted, adjectively, to apply to a structure which is neither straight as to alignment, level as to gradient, symmetrical as to transverse loading, nor orthodox as to the tenet of design which requires that indeterminate stresses must be solved by being avoided. Mr. Green.

Moreover, it is unique in that the embellishments of art have been invoked, with very gratifying success, to commend to the esthetic emotions a structure primarily intended to be useful. This, too, under circumstances most unpropitious—an ugly *situs*, an unbalanced subject, and an inauspicious environment; and, as the author states, "without any extra funds for adornment".

A consideration of the problem creates a feeling of dismay, which is superseded later by one of admiration for the ingenuity shown and the resource developed in mastering the many baffling features. To the mind mathematically inclined, the graphical method for solving the integrals shown on pages 494 and 495 will commend itself both for elegance and simplicity. The method for obtaining moments and deflections for the rectangular frames (given on page 496) by the solution of ten simultaneous equations, though no laughing matter, offers opportunity for mirth: "When a structure is so formed that the stresses in it cannot be determined by statics, it is said to be a redundant system; and the principle of least work applicable to it is as follows, etc."† Do we not have here a paradox? Is it strictly proper to say that the solution of these ten simultaneous equations involves the principle of least work? The author says: "By arranging these * * * in tabular form, the solution is found with comparatively little labor." Did he intend "little" in the sense of *"multum in parvo"*?

Seriously speaking, however, the impression uppermost in the writer's mind, after reading this paper, is that this work marks another important instance of the present tendency in American development to pass from the stage of pioneer civilization, with its temporary, but economical and expedient, types of buildings, works, ways, and systems, to an era of permanence, beauty of line and mass, sufficiency, and efficiency.

The design of this structure is a bold departure in many respects from the established canons of design, and the novice should be admonished not to undertake liberties of this kind unless and until he is absolutely sure of his ground. For example, a comparatively slight settlement of the foundation under one of the 120-ft. columns conceivably might have disastrous consequences.

* Stamps, Ark.
† Merriman's "Mechanics of Materials", 10th Ed., p. 321.

Mr. Mensch.

L. J. MENSCH,* M. AM. SOC. C. E. (by letter).—Reinforced concrete seems to enlist the brightest engineers under its colors. Though viaducts like that described in this paper have often been built of steel, one would search American literature in vain for a description of such viaducts in which the attempt was made to design the structure for temperature and other so-called secondary stresses, as was done for the Twelfth Street Trafficway Viaduct of Kansas City. Because such refined—but often very necessary—computations are rare in American practice, we need not be surprised that, in one of the first attempts, such computations lack the simplicity, elegance, and surety of the

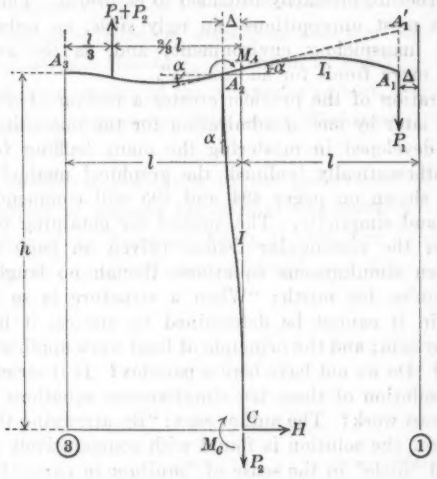

FIG. 26.

schooled designer. Not until a great many of our students take post-graduate courses in the design of so-called "higher structures" can a material change be expected in this matter. Take, for example, Fig. 2 and its explanation. The writer has designed indeterminate structures for more than twenty years, yet he can follow the reasoning only with great difficulty. There is no need for such lack of clearness.

The problem can be solved entirely with much less effort, by finding the unknown conditions of the supports at A_1 and C (Fig. 26). A sliding joint was assumed at A_1, hence the only unknown that can act there is the vertical force, P_1. The point, C, is fixed, hence the support will exert on the column, A_2 C_1, a thrust, H, a pull, P_2, and a moment, M_C.

* Chicago, Ill.

Mr. Mensch.

These unknown reactions can easily be found by the rules for the change of angles and for the deflection of a beam:

$$\Delta\alpha = \int \frac{M ds}{E I} = \frac{1}{E I} \text{ (area of diagram of moment)} \ldots\ldots\ldots\ldots (1)$$

$$\Delta y = \int \frac{M x ds}{E I} = \frac{1}{E I} \text{ (static moment of diagram of moment about the point, the deflection of which is sought)} \ldots (2)$$

For the force, P, acting at the end of a cantilever,

$$\Delta\alpha = \int \frac{P x dx}{E I} = \frac{P l^2}{2 E I}$$

$$\Delta y = \int \frac{P x \times x dx}{E I} = \frac{P l^3}{3 E I}, \text{ provided } I \text{ is constant.}$$

$A'_1 A_1$ can be considered the deflection of the point, A_1, due to P_1, or

$$l\alpha = \frac{P_1 l^3}{3 E I_1},$$

or

$$\alpha = \frac{P_1 l^2}{3 E I_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

It is true, as the author has stated, that the point of inflection of $D B$ is $\frac{1}{3}\ l$ from D, and, in order to preserve the equilibrium, we can imagine that P_1 and P_2 are acting at this point, producing a moment, $(P_1 + P_2)\ \frac{l}{3}$, at A_3, and $(P_1 + P_2)\frac{2}{3}\ l$, at A_2.

Then

$$\alpha = \frac{(P_1 + P_2)\frac{2 l}{3} \times \frac{2 l}{3} \times \frac{1}{2} - (P_1 + P_2)\ \frac{l}{3} \times \frac{l}{3} \times \frac{1}{2}}{E I_1}$$

$$= (P_1 + P_2)\frac{l^2}{6 E I_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

From Equations 3 and 4, $\frac{P_1 + P_2}{6} = \frac{P_1}{3}$,

or

$$P_1 = P_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (5)$$

We can determine, also, from the column, $A_2\ C$,

$$\alpha = \frac{M_c h - \frac{H h^2}{2}}{E I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

and from Equations 3 and 6, $\frac{P_1 l^2}{3 E I_1} = \frac{M_c h - \frac{H n^2}{2}}{E I}$

Mr. Mensch. let $n = \frac{h}{l}\frac{I_1}{I}$, $\qquad M_c\, n - \frac{H h\, n}{2} = \frac{P_1 l}{3}$ .....(7)

From $A_2 C$,

$$\Delta = \frac{\frac{M_c h^2}{2} - \frac{H h^3}{6}}{E I}, \text{ or } M_c - \frac{H h}{3} = \frac{2 E I}{h^2}\Delta \text{ .....(8)}$$

By taking moments about A_2,

$$(P_1 + P_2)\frac{2}{3} l + P_1 l + M_c = H h \text{ .....(9)}$$

Equations 7, 8, and 9 have three unknowns, and we easily obtain

$$\left.\begin{aligned} H h &= \frac{2.4\, E I}{h^2}\Delta \frac{1 + 7 n}{1 + 2.8 n} \\ M_c &= \frac{2.4\, E I}{h^2}\Delta \frac{1 + \frac{7}{2} n}{1 + 2.8 n} \\ P_1 l &= 3.6\, E \frac{I}{h^2}\Delta \frac{n}{1 + 2.8 n} \\ M_A &= 8.4\, E I \times \frac{\Delta}{h^2} \times \frac{n}{1 + 2.8 n} \end{aligned}\right\} \text{ .....(10)}$$

If the structure is cast monolithically, without any joints, we can place $I = \frac{b \times d^3}{12}$.

The moment of resistance $= \frac{b \times d^2}{6}$, and

the stresses at $C = \frac{M_c}{\frac{b \times d^2}{6}} = \frac{2.4\, E \frac{b \times d^3}{12}}{\frac{b \times d^2}{6}} \frac{\Delta}{h^2} \frac{1 + \frac{7}{2} n}{1 + 2.8 n}$

$$= 1.2\, E\, d \frac{\Delta}{h^2} \frac{1 + \frac{7}{2} n}{1 + 2.8 n} \text{ .....(11)}$$

The moment of inertia of the columns varies, and, assuming the section of the base only to govern, $n = 4.46$; of the top only to govern, $n = 2.76$, which produces hardly any difference in the value of the fraction, $\frac{1 + \frac{7}{2} n}{1 + 2.8 n}$, as the respective quotients are 1.23 and 1.233.

Assuming $d = 7$ ft., $l = 48$ ft., $h = 89$ ft., $E = 3 \times 10^6$, $\Delta = \frac{l}{2\,000}$, then $S_c = 94$ lb. per sq. in.

Mr. Mensch.

Where the bents are $h = \frac{89}{4} = 22$ ft. 6 in., S_c is nearly sixteen times as great, or 1 504 lb. (the value of $\frac{1 + \frac{7}{2} n}{1 + 2.8 n}$ changing only to 1.2), which is not counterbalanced by the dead load of the structure, and large cracks will be prevented only by steel reinforcement.

In this case, $E I$ must be replaced in Equation 10 by $E_s A_s d'^2$, where E_s is the modulus of elasticity of the steel, A_s is the steel reinforcement, in square inches, on the tension side, and $d' = jd$, the moment of resistance being represented by $A_s jd$.

The stress in the reinforcement at C

$$= \frac{2.4 E_s A_s d'^2 \frac{\Delta}{h^2} \frac{1 + \frac{7}{2} n}{1 + 2.8 n}}{A_s d'} = 2.4 E_s \frac{d'}{h^2} \Delta \frac{1 + \frac{7}{2} n}{1 + 2.8 n} \quad \ldots\ldots(12)$$

In this latter case, M_c is of considerable magnitude, and will cause an unequal loading of the piles, the latter being symmetrically arranged around the columns.

Evidently the author forgot to assume a thrust at C, or he would have found that M_2, in Fig. 3 must be negative, if he considers M_1 positive.

It is absolutely unnecessary to resort to the summation methods, where the expression, $\frac{d s}{I}$, varies.

In most cases we can put $\frac{d s}{I} = \frac{d x}{I}\left(1 + C\frac{x}{l}\right)$, which will allow of easy integration of $\frac{M d s}{I}$ and of $\frac{M x d s}{I}$.

It is extremely rare, where, instead of a straight-line variation, a parabolic, or hyperbolic variation of $\frac{d s}{I}$ must be adopted.

The advantage of integration over summation is evident by the fact that in the first case we can obtain a formula of general application, but in the latter we obtain the solution of one particular problem only.

The use of the formulas for continuous beams for solving stresses in framed structures is accompanied with great difficulties, and is not the shortest or most lucid solution of the problem.

Any one reading the author's method of finding the wind stresses in a two-story frame, would think it requires the enormous labor of solving a six times indeterminate structure, even if both columns have the same moment of inertia. Such a structure is only twice indeterminate. On account of the symmetry of construction, the point of inflection of the girders must be the center of the span. By the same

Mr. Mensch.

method as the writer used for the temperature stresses, the following equations may be found to solve for P_1 and P_2:

$$\frac{I_1}{I_2} P_2 = P_1 + 6\, n_1 \times P_1 - 6\, \frac{M'\, n_1}{l} \quad \ldots\ldots\ldots\ldots (13)$$

$$0 = P_2 + 6\,(P_1 + P_2)\, n_2 - 6\, \frac{M''\, n_2}{l} \quad \ldots\ldots\ldots\ldots (14)$$

When $n_1 = \frac{h_1}{l}\,\frac{I_1}{I}$, $n_2 = \frac{h_2}{l}\,\frac{I_2}{I'}$, and $M' = \frac{H_1 h_1}{2}$, and $M'' = H_1\left(h_1 + \frac{h_2}{2}\right) + H_2\,\frac{h_2}{2}$.

Where the moments of inertia of the columns are not alike, the exact solution, as above stated, is very laborious, and mostly time and men are lacking to do such work; but, fortunately, we can find an approximate solution, by considering that P_1 and P_2 vary only slightly from the values obtained from Equations 13 and 14, and that the point of inflection of the girders moves only very slowly from the center toward the weaker column. Where the ratios of the moments of inertia of the columns is infinite, the point of inflection would be at the connection of the girder and the weaker column; in the Twelfth Street Trafficway Viaduct it is about $\frac{3}{10}\, l$ from the weaker column. The assumption of the point of inflection is easily checked by calculating the deflection at the top of the frame. The deflection of the left column must be equal to that of the right, and if at the first trial they are not alike, a good guess will serve to make them so.

By comparing Fig. 27 with Fig. 7 it should be noted that the columns show one point of inflection at B and one midway between B and C, which were omitted by the author.

The equation for the funicular line of an arch, as shown in Fig. 8, saves considerable time over the graphical method generally used in arches with earth fill, but it is not a very fair approximation in an arch of open spandrel construction. In the latter case it is more correct to assume that $P_s - P_c$, the difference of weight per linear foot at abutment and crown, respectively, decreases to zero according to a straight line from the abutment to the crown, in which case the equation of the funicular polygon is

$$y = \frac{4\,h}{l^2}\,\frac{3\,x^2 + 2\,(u-1)\,\frac{x^3}{l}}{2+u},$$

and the corresponding thrust $= \frac{P_c\, l^2}{8\,h}\left(1 + \frac{(u-1)}{3}\right)$.*

* The equations for both cases might be found in the writer's "Reinforced Concrete Pocketbook", where also the ordinates of the curves are calculated in fractions of h for various values of u.

Mr. Mensch.

The summation method of finding the statically unknown value of the thrust, reaction, and moment of the abutment, requires very lengthy computations, with great likelihood of numerical and other errors. The writer can state positively that such errors must have been made when finding the influence lines, as the apex of the influence line for moments due to vertical loads at Point 6 should have been higher than at Point 8, on Plate XVII; and the apex at Point 0 should have been at least 8% lower than at Point 2.

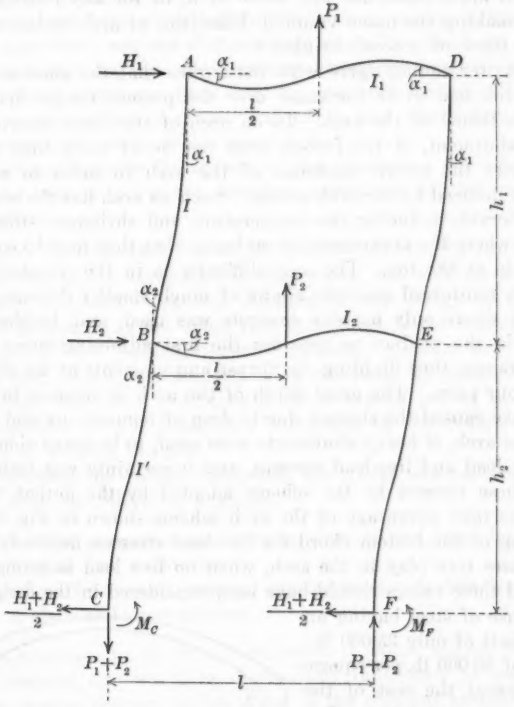

FIG. 27.

It is well known that Howe and many other writers have given very simple formulas for the statically indeterminate values of a parabolic arch with constant $\frac{ds}{I}$; but there nearly all writers have stopped. The question is often asked: can these formulas be applied to arches with varying $\frac{ds}{I}$, and of correct shape to suit the earth fill?

Mr. Mensch.

In most cases they can be applied directly for live loads, but they fail widely for temperature and shrinkage stresses. As indicated before, $\frac{ds}{I}$ may be put $= \frac{dx}{I}\left(1 + C\frac{x}{l}\right)$ and, instead of a parabolic curve, the one given by the author accompanying Fig. 8 can be used. The work necessary to integrate the elastic equations is not greater than the numerical work of the summation method, and the results are formulas of general application, for any value of u, or for any relation of rise to span, making the much vaunted difficulties of arch design nearly as small as those of a common girder.

The writer cannot agree with the author that the abutment of the 130-ft. arch had to be increased over the present design in order to resist the thrust of the arch. In an arch of the shape shown in Fig. 28, the abutment, if reinforced, need not be of more than twice or three times the crown thickness of the arch in order to resist the moments induced by the arch action. Such an arch has the advantages of considerably reducing the temperature and shrinkage stresses over a design where the abutments are so heavy that they may be considered immovable at the top. The only difficulty is in the foundations, but also here, reinforced concrete allows of much smaller dimensions than formerly, where only massive concrete was used, and, besides, it was possible in the viaduct to consider the first adjoining spans at each side as frames, thus dividing the thrust and moments at the abutments among four piers. The great depth of the arch in relation to the rise would have caused the stresses due to drop of temperature and shortening of the arch, if heavy abutments were used, to be many times larger than the dead and live-load stresses, and it certainly was fortunate to reduce these stresses by the scheme adopted by the author, after he omitted to take advantage of the arch scheme shown in Fig. 28. The shortening of the bottom chord for live-load stresses, however, brought new stresses into play in the arch, when no live load is acting on the arch; and their values should have been considered in the design.

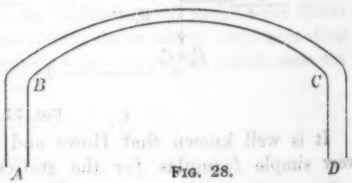

FIG. 28.

The use of steel having an elastic limit of only 35 000 lb., instead of 50 000 lb. per square in., increased the cost of the structure about $40 000. The writer cannot understand the prejudice of engineers against the use of a higher grade of steel, made of billet stock, in reinforced concrete construction. All tests made by the best-known authorities show that the ultimate carrying capacity is increased by its use by more than 50% over low-carbon steel. There certainly is a very small chance that shock

will affect the steel in columns or footings, or that the small steel bars in the slabs will be affected by shocks. The only place where an engineer may properly doubt the advisability of using high-carbon steel reinforcement is in the bent bars of girders, because the bars are often injured by careless bending. Where careful bending is done, with large radii, say about six to ten times the diameter, no engineer need be afraid of any unfavorable results. The writer used high-carbon bars for the reinforced floors of the Utah copper concentrator, in Garfield, Utah, and although about 8 000 tons of material have been vibrating 1 000 000 times a day, without interruption since 1907, not the slightest sign of failure has been detected. Mr. Mensch.

The provision in the specifications requiring bars to be firmly bound and tied together where they lap was unfortunate. The stress in bars is transmitted by shear and bond, and where bars are tied together the bond surfaces are decreased.

The author deserves the thanks of the Profession for offering this paper, and especially for the detailed description of the methods of construction.

HOWARD W. HOLMES,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer is very much interested in this paper, not only on account of the several uncommon features involved in the design of the structure, but because it is not often that structures of the magnitude and importance of the Twelfth Street Trafficway Viaduct are described as fully and clearly, particularly with reference to arch design and construction features. Publications of this kind are of great value to all members of the Profession interested in the design and construction of modern bridges. Mr. Holmes.

In reviewing the details submitted, the writer was particularly impressed with the following features:

First.—The unequal cross-sectional area of the main longitudinal girders and arch ribs;

Second.—The curved tension reinforcement in the longitudinal girders and cross-girders.

With reference to the first mentioned, it would appear that members of unequal size would be dissimilarly influenced by temperature changes, causing thereby undue stress in the columns and floor system which would combine with the secondary stresses induced by the rigid connections of the upper and lower decks. The arch ribs, owing to their unequal size, would undoubtedly, when subjected to temperature changes, exert a like influence on the spandrel columns and supported deck, resulting in strains and cracks in the floor system and weaker members, though granting certain elastic deformation through-

* Portland, Ore.

Mr. Holmes.

out the system. The stress induced as above, combined with the possible variation in temperature between the arch ribs and lower chords, should, in the writer's opinion, merit consideration. The possibility of the dissimilar temperature influence is further emphasized by the fact that the lighter members are all on the south, or more exposed side of the structure. The effects of these stresses might be modified, but not eliminated, by constructing expansion joints at the intersection of the arch axis and the line of temperature thrust, or at the spandrel columns nearest this intersection.

It is gratifying to note the thorough and systematic methods followed in the arch analysis, and that the method of influence lines is coming into more general use, as it is certainly the only method that can be relied on for structures subjected to the severe concentrations imposed by modern traffic. Under the common loadings of several years ago, it was thought sufficient to consider the arch under two or three conditions of loading. This method, though still used to a great extent, is entirely inadequate, and, if applied, gives no assurance that the maximum stresses in the arch have been determined. Failures have been averted only by providing an excess of material; but, at the present day, when economy of design is considered a factor of major importance, a more exact method of loading must be adopted. Since the position of the live load producing maximum moment at any point will vary in arches of different proportions and form, modern practice makes it imperative, in the interests of safety and economy, that the more complete and exact method of analyzing an arch for a load of unity at each load point be used. Influence lines may then be drawn for both the upper and lower fibers, and the exact maximum values due to both vertical and horizontal loads, either uniform or concentrated, may be determined, as the influence lines will show clearly the extent and general position of the loads for maximum stress. Undoubtedly, the design of an elastic arch is one of the most delicate problems of structural engineering, but if the designer is sufficiently familiar with his work, it may be performed without great difficulty. It is only by applying rational and systematic methods, such as were used in the design of the structure under discussion, and combining the economical design evolved with faultless construction, that the field of usefulness of this esthetic form of structure will become more generally recognized.

The author has used the method of constructing influence lines for moment and thrust. By constructing these lines for stress in extreme fiber, a great deal of time may be saved by applying a modification of the stress equation for homogeneous beams,

$$S = \frac{M}{\frac{I}{c}},$$

Mr. Holmes.

where S = stress in extreme fiber,
M = maximum sectional bending moment,
I = moment of inertia,
and c = distance to neutral axis.

When the fiber stress is wholly compression, and considering the additional factors,

r = least radius of gyration,
N = thrust normal to the section,
A = area of transformed section,
I' = moment of inertia of transformed section,
and e = eccentricity,

the unit stress in the concrete will be $\frac{N}{A}$, and the unit flexural will be $\frac{Mc}{I'}$. Considering the combined section, we have

$$(M\,c\,A) + (N\,I') = S\,A\,I',$$

$$\text{or } S = \frac{N}{A} + \frac{M\,c}{I'}.$$

Equating $A\,r^2 = I'$, and $M = N\,e$, we have

$$S = \frac{M'\,c}{I'}, \text{ where } M' = N\left(e + \frac{r^2}{c}\right).$$

Computing the values of $\frac{r^2}{c}$ for the various sections, and considering this distance as the moment arm, and the fiber stress as varying as the moment, an influence line drawn for the moments thus computed will serve directly as an influence line for fiber stress. The writer has found that this direct method eliminates many chances for error, and saves considerable time. Of course, when the tensile stress in the concrete is ignored, as it should be, and the resultant stresses are tensile, it will be necessary to plat the influence lines for moment and thrust, and compute the stress in extreme fiber in the usual manner.

In connection with the discussion of stress in an arch of this type, a most important feature is the method of construction. The writer believes that cracks and initial stresses, as often developed, may be traced directly to the construction methods, and a description of the latter would complete this valuable paper.

With reference to the curved tension reinforcement in the longitudinal and cross-girders, it may not be unreasonable to ask why the main tension reinforcement was not placed in a horizontal position, and lighter and shorter lengths of steel bars used to reinforce the haunches. It appears to the writer that the method used

Mr. Holmes.

does not accomplish the results in the most economical way. Although the distribution of metal throughout the girders is ideal, it would appear that the same results could be accomplished with a smaller quantity of steel.

As shown by the following demonstration (see Fig. 29):

Let P = total stress in bar;
p = normal pressure per linear unit;
ds = single element.

Then the vertical component $= p\,ds$; $\cos.\,\theta = pr\,d\,\theta$; $\cos.\,\theta = X$.

$$\Sigma\,X = \int_c^B pr,\cos.\,\theta,\,d\,\theta + c = pr\,\sin.\,\theta + c.$$

$\Sigma\,X = 0$ when $\theta = 0$, therefore $c = 0$.

$$\Sigma\,X = pr\,\sin.\,\theta \quad \ldots\ldots\ldots\

Mr. Holmes.

On the other hand, it would not be economical to compensate for the effect of the vertical components of force by increasing the sectional area of metal at the critical section.

The distribution of the summation of the vertical forces referred to would follow the sine curve and result in considerable increase of moment at the center of the girder.

The painstaking care exercised by the designers in the close attention to details is to be commended, as there is very little to be guessed at by the prospective builder in figuring his estimates of costs.

Another important feature, in the writer's opinion, was the exclusion of piles in which fresh or unset concrete is placed against the soil. Considerable experience in connection with concrete piles under various subsoil conditions has demonstrated conclusively, to the writer's satisfaction, that reliable results in this most important feature of foundation work may be expected only by using piles in which the unset concrete is not allowed to come in contact with the subsoil. The many failures resulting from the use of concrete piles constructed in immediate contact with the soil should fully justify the statement that those of the latter type are not to be recommended where permanent and reliable results are desired.

The writer is pleased to note that the conventional sand cushion under the wood block pavement has been omitted. Considerable experience on the writer's part in constructing wood block pavements on bridge floors and reconstructing the floor systems of various bridges has demonstrated that the blocks are bound to heave and buckle, due to the shifting of the sand cushion, particularly when laid on a grade. The sand cushion will also give trouble where the blocks are laid with open joints, owing to the possibility of water leaching through the joints and displacing the cushion. The method used by the author has many advantages, and effectively water-proofs the bottom of the blocks.

Owing to the great variety of traffic that will no doubt be carried by this viaduct, it will be interesting to note the results obtained, under various climatic conditions, by constructing a wood block pavement on a grade of 5.5% and using the ¾-in. lath separators between the rows. This method has been tried before, but it would seem that observation of the great variety of types of street users that may be expected to pass over this structure will result in interesting and valuable data.

In reviewing the paper, one cannot help being most favorably impressed with the fact that, in drafting the specifications, an effort was made to eliminate as far as possible the uncertain characterization of work "satisfactory to the engineer", to make perfectly clear to the prospective builder just what was to be required, and to express the views of the engineer in advance. The writer does not wish it

Mr. Holmes.

to be inferred, however, that the engineer should have no discretion whatever in regard to carrying out the contract, but it may be unhesitatingly stated that this feature is one of the most important matters before the Engineering Profession to-day. The "satisfaction" of an engineer is a factor over which the contractor has no control, and it would be possible for a contractor to perform work absolutely above criticism, and yet not be able to compel the engineer to be "satisfied". Most contractors take pride in their work, and, as a matter of business policy and to maintain a reputation as a reliable contractor, make conscientious efforts to perform their work to the satisfaction of the engineer. Reliable contractors realize that competent supervision on the part of the engineer is absolutely essential. The making of a contract to the effect that work shall be performed to the "satisfaction of the engineer" and the letting of contracts without advance engineering information have been responsible for considerable pooling and combination in the contract business. The very idea of contracting to perform certain work is that such work can be planned and estimated in advance, as a result of experience with similar work, under like conditions, so that the contractors may have full knowledge of what is to be required and be able to fix with reasonable accuracy the cost of performing it. Contract work should be confined to that which involves quantities and conditions which may with reasonable certainty be determined in advance by experienced engineers. Work which cannot be determined in this way should be let on a basis of reasonable cost, plus a just percentage for profit. It should be clearly understood, however, in this latter case, just what items should be included in the cost.

In defense of the Profession, however, it should be considered that many of the weaknesses of specifications governing, or supposed to govern, public work may not be the fault of the engineer, as it is undoubtedly true that many of the absurd and unjust requirements, which are injurious both to contractors and to the public, are provided by law and by city charters. That many of the clauses found in public work specifications are not necessary is shown by the faithful and satisfactory completion, by contractors all over the country, of contracts with business firms where no such clauses are considered necessary, and where there exists recognition of the relation between the responsibility of the contractor and the requirements for the bond and retained percentage.

One of the main reasons that public work is often more expensive and less satisfactory than work contracted for by private firms is the fact that most of our laws compel the award to the lowest bidder. This, combined with the many other uncertain requirements, has in many cases proved most injurious to the public welfare.

Mr. Holmes.

It is quite generally supposed that profits from public work contracts are so great that anything that can be imposed on the contractor is so much clear gain. Needless risk should not be imposed on a contractor. Any one possessing an elemental knowledge of business principles should know that no competent and financially responsible contractor will take a gambling risk without charging enough on his bid to save himself from loss. Of course, there are contractors who will bid low in order to obtain the work, but, in the majority of cases, they are either financially irresponsible, or shrewd enough to make up their loss by slighting the work. Work let to the contractor of this latter class is bound to cost in the long run a good deal more than had it been let to a competent and reliable man who understands his business.

The writer has had considerable experience in contract work, both public and private, and has learned to appreciate the integrity and desire of contractors to perform work creditable to their reputation. The Profession should stand as a unit in making an effort to overrule the many unfair clauses of almost universal use in specifications, as these clauses have their part in limiting competition, in lowering the standard of honesty among contractors, and in lessening the dignity and standing of the Profession. By cultivating the confidence of reputable contractors and providing for competitive bidding on public contracts, immense sums may be saved to the taxpayers. A continuation and more wide-spread adoption of the policy followed by the engineers in connection with the contract for the structure under discussion will accomplish the desired results. The author deserves the thanks of every member of the Profession for his effort.

Mr. Upson.

M. M. Upson,* Assoc. M. Am. Soc. C. E. (by letter).—As is usual in a descriptive paper of this character, limited space has prevented Mr. Howard from taking up in detail the reasons for selecting the component parts of the structure. In particular, a short account of the selection of Raymond piles by the contractor, and their acceptance by the engineers, will show the care and forethought which characterized this entire work, and can now be seen to have saved both time and money.

Up to 1912, with one exception, the only concrete piles used in Kansas City were pre-cast. Mr. Howard had used pre-cast piles on a somewhat similar viaduct within half a mile of the present structure. It was natural, therefore, that the specifications should allow pre-cast as well as cast-in-place piles, the latter being limited to those in which "fresh or unset concrete is not placed against the soil." Pre-cast piles 25 ft. long were estimated as being necessary, it being provided that a variation in length could be ordered if required when the

* New York City.

Mr. Upson.

work began, and it was specified that such piles were to be jetted into place.

The soil of the site is a typical Missouri River fill overlying a very fine and comparatively clean sand, admirably suited to jetting, and into which the contractor would have experienced no difficulty in placing the 25-ft. pre-cast pile. On the east end of the viaduct, where it approaches the rock cliff, erosion subsequent to the initial placing of the soil had evidently taken place, as the sand and rock were covered with a very soft muddy material which necessitated piles at least 30 ft. long.

It is apparent that had pre-cast piles been used, about 10% of their total number would have been increased fully to 30 ft. in length on this account. The remainder, by the use of a jet, would have penetrated 25 ft., so that the 2 610 piles would have totaled 66 555 lin. ft.

After a careful study of the conditions, Raymond piles were selected. They were driven without jetting to a sufficient penetration to support safely the maximum load of 35 tons each. By driving to an agreed penetration to the last inch, a uniform bearing value was obtained, the lengths varying to meet the different soil conditions. They ranged from 12 to 30 ft., and in some individual piers there was a length variation of as much as 5 or 6 ft. By the use of the Raymond system, it was unnecessary to predetermine the lengths of the piles, and the city paid for only the actual number of feet driven. In this instance, the 2 610 piles totaled 46 625 lin. ft., which showed a saving of 19 930 ft. over the prescribed 66 550 lin. ft. of pre-cast piles. At the contract price, $1.20 per ft., this saved the city about $24 000, or 43% of the total cost of the piling.

It may be well to point out one or two reasons why, in the writer's opinion, a less length of pile may safely carry the same load. In this instance, as in most pile installations, the piling element does not penetrate to rock or hardpan, but carries its load by surface friction. The friction per square foot of surface in a given soil is dependent on several factors:

1.—The angle between the soil and the surface. It is obvious that the friction on a vertical surface can be no more than the shear of the adjacent soil, though the friction on a perfectly horizontal surface will be equivalent to the compressive strength of the soil. The vertical surface friction varies between these two limits. On that account a tapered friction pile has a great advantage over the straight cylindrical pile. The writer has frequently tested tapered piles to a surface friction of more than 2 000 lb. per sq. ft. without rupture.

2.—The degree of compression of the soil which is attained by the driving. This depends on the amount of abuse to which the driven

pile or form may be subjected. The necessary cushion to protect the concrete of a pre-cast pile limits its effectiveness in this function. Mr. Upson.

3.—The maintaining of the compression after it has been attained through the driving. This is effectively accomplished in the pre-cast pile, as it is also in the Raymond type, with its spirally reinforced and corrugated shell, which is left in the ground.

In addition to the saving of cost by reason of the shorter lengths required, the use of Raymond piles avoided a difficulty which would undoubtedly have proved both costly and troublesome to the contractor. This is the operation of jetting on the site.

The work was in a congested district, with unusually heavy street and railroad traffic. Had pre-cast piles been used, the disposal of the water from the jets would have been a great problem. A filter of some kind would have been required to separate the sand from the water, as the sewers in that part of Kansas City have a very small fall, which would prevent them from carrying water containing any large quantity of sand.

The jetting of piles in a city always entails many difficulties, especially when fine and light soil, easily carried in suspension, is encountered. It is, of course, quite impossible to carry the water on the surface, because of streets and crossings which occur at close intervals. It will be seen, therefore, that, by avoiding this difficulty, the contractor saved himself much annoyance and expense.

Time is another factor of economy affected by the use of Raymond concrete piles on this work. Had pre-cast piles been used, most of them would have been cast during the winter. A minimum time of 30 days was specified, and under ordinary winter conditions this time would have been doubled before the piles had cured sufficiently to be safely handled. As a matter of fact, the weather during this work was unusually mild, so that the temperature delay would not have been serious. However, the necessary 30 days after the receipt of the reinforcing rods, which usually requires several weeks for delivery on the ground, necessitates an interval of from 6 to 8 weeks between the signing of the contract and the placing of the footings. Furthermore, a slight variation in the underlying soil conditions may involve the contractor in a further delay of from 30 to 60 days, in order to provide longer piles to meet the varied requirements.

The actual money saving by cutting down the time is frequently lost sight of by the contractor as well as by the owner. After a construction project is determined on, and the preparations are made, the money loss to the owner usually can be computed accurately, and often amounts to several hundred dollars a day, and all wise contractors readily realize the fact that their profit, under ordinary conditions, is inversely proportional to the time required to complete the work. Sev-

Mr. Upson.

eral instances have come to the writer's attention where the loss to the owner and a proportional amount to the contractor, on account of the delay incident to choice of improper foundation methods, has involved a sum greater than the total cost of the foundation itself.

To summarize: Raymond piles were selected, first, because of the saving in length, which, in this instance, amounted to 43%, or $24 000, on the total expenditure of $56 000; second, the saving of time, which may be estimated at not less than 30 days, as the footings and superstructure followed very closely on the driving of the piles; third, the avoidance of annoying and expensive pumping equipment and methods for taking care of waste water incident to the jetting.

Mr. Slettum.

E. A. SLETTUM, ESQ.* (by letter).—The investigation of the columns for the Twelfth Street Trafficway Viaduct was made by the writer, then in the employ of Waddell and Harrington, the designers of the structure, as Assistant Engineer. On account of the great number of columns and their size, it was of the greatest importance, in order to obtain an economical and safe structure, to determine, with as great precision as practicable, the various bending moments that might occur. The most difficult problem was the determination of

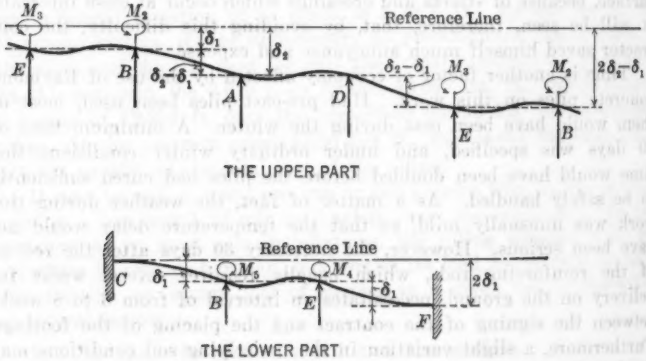

FIG. 29.

bending moments due to wind loads. A typical bent, as shown by Fig. 6, was chosen, and the problem was solved, as mentioned, by breaking the frame up into two parts, one upper part, *ABED*, and one lower part, *BCFE*, the cross-girder, *BE*, being common for both. The two parts were then straightened out, as shown in Fig. 29, and calcu-

* Christiania, Norway.

lated as continuous beams on supports at different levels, the internal moments, M_2 and M_3, of the lower part acting as external moments on the upper part, and, *vice versa*, the internal moments, M_4 and M_5, of the upper part acting as external moments on the lower part. Mr. Slettum.

The frame was assumed to be rigidly fixed at the bases, C and F. All members of the frame, except the cross-girder, BE, had variable cross-sections, and, therefore, the three-moment equation for beams with variable moments of inertia was used. This equation, not being published in any book known to the writer, was developed by him in connection with this work, and may possibly be of some interest.

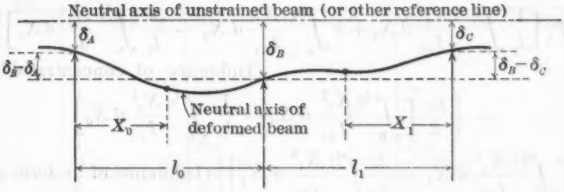

FIG. 30.

Let ABC be any three consecutive supports in a continuous beam;

I_{X0} be the general value of the moment of inertia in the left-hand panel (Panel AB);

I_{X1} be the general value of the moment of inertia in the right-hand panel (Panel BC);

X_0 be the distance from the left-hand support to any point in the left-hand panel;

X_1 be the distance from the right-hand support to any point in the right-hand panel;

P_0, p_0, and M_0, respectively, be any concentrated load, uniform load per unit, and external bending moment, in the left-hand panel.

P_1, p_1, and M_1, respectively, be any concentrated load, uniform load per unit, and external bending moment, in the right-hand panel;

kl_0 and kl_1 be the distances, respectively, from the left-hand support in the left-hand panel and from the right-hand support in the right-hand panel, to any concentrated load or external bending moment;

E be the modulus of elasticity of the material; and

M_A, M_B, and M_C be the internal moments (continuity-moments) at A, B, and C, respectively.

Mr. Slettum.

Then, with the notation shown in Fig. 30, the three-moment equation for beams with variable moments of inertia is written thus:

$$M_A\left[\frac{1}{l_0}\int_0^{l_0}\frac{X_0}{I_{X0}}\,dX_0-\frac{1}{l_0^2}\int_0^{l_0}\frac{X_0^2}{I_{X0}}\,dX_0\right]$$
$$+M_B\left[\frac{1}{l_0^2}\int_0^{l_0}\frac{X_0^2}{I_{X0}}\,dX_0+\frac{1}{l_1^2}\int_0^{l_1}\frac{X_1^2}{I_{X1}}\,dX_1\right]$$
$$+M_C\left[\frac{1}{l_1}\int_0^{l_1}\frac{X_1}{I_{X1}}\,dX_1-\frac{1}{l_1^2}\int_0^{l_1}\frac{X_1^2}{I_{X1}}\,dX_1\right]$$
$$=-\Sigma\left\{P_0\left[\frac{1}{l_0}\int_0^{k\cdot l_0}\frac{X_0^2}{I_{X0}}\,dX_0+k\int_{k\cdot l_0}^{l_0}\frac{X_0}{I_{X0}}\,dX_0-\frac{k}{l_0}\int_0^{l_0}\frac{X_0^2}{I_{X0}}\,dX_0\right]\right.$$
$$\left.+P_1\left[\frac{1}{l_1}\int_0^{k\cdot l_1}\frac{X_1^2}{I_{X1}}\,dX_1+k\int_{k\cdot l_1}^{l_1}\frac{X_1}{I_{X1}}\,dX_1-\frac{k}{l_1}\int_0^{l_1}\frac{X_1^2}{I_{X1}}\,dX_1\right]\right\}$$

(Influence of concentrated loads)

$$-\left\{\frac{p_0}{2}\left[\int_0^{l_0}\frac{X_0^2}{I_{X0}}\,dX_0-\frac{1}{l_0}\int_0^{l_0}\frac{X_0^3}{I_{X0}}\,dX_0\right]\right.$$
$$\left.+\frac{p_1}{2}\left[\int_0^{l_1}\frac{X_1^2}{I_{X1}}\,dX_1-\frac{1}{l_1}\int_0^{l_1}\frac{X_1^3}{I_{X1}}\,dX_1\right]\right\}$$

(Influence of uniform loads)

$$-\Sigma\left\{M_0\left[\frac{1}{l_0^2}\int_0^{l_0}\frac{X_0^2}{I_{X0}}\,dX_0-\frac{1}{l_0}\int_{k.l_0}^{l_0}\frac{X_0}{I_{X0}}\,dX_0\right]\right.$$
$$\left.+M_1\left[\frac{1}{l_1^2}\int_0^{l_1}\frac{X_1^2}{I_{X1}}\,dX_1-\frac{1}{l_1}\int_{k.l_1}^{l_1}\frac{X_1}{I_{X1}}\,dX_1\right]\right\}$$

(Influence of exterior bending moments or pairs of forces)

$$+E\left[\frac{\delta_B-\delta_A}{l_0}+\frac{\delta_B-\delta_C}{l_1}\right]$$

(Influence of yielding supports, or supports at different levels).

In this equation, P and p are introduced with positive sign when producing tension on the under side of a beam freely supported on two supports, and M is introduced with positive sign when producing tension on the under side of the beam between the left-hand support and the point of application in the left-hand span (that is, when acting counter clockwise), and between the right-hand support and the point of application in the right-hand span (that is, when acting clockwise).

The work was somewhat simplified in this case by having no other exterior loads with which to deal, other than the bending moments at B and E. The quantities, $\int\frac{X}{I}\,dX$, $\int\frac{X^2}{I}\,dX$, etc., were determined graphically in the manner indicated by Fig. 5.

On the basis of these calculations, the writer has devised a more general application of the theory of the continuous beam to problems of this nature, which is set forth in the following discussion.

Mr. Slettum.

He does not believe that the method will be used to any great extent, except for rather simple frames, the labor of solving the many equations being enormous, on account of the calculations having to be carried through with the most rigid accuracy and to the last decimal point, in order to obtain correct results, the slightest rounding off resulting in an error which increases rapidly with the number of equations.

FIG. 31.

For problems, such as the case in hand, having not more than eight or ten statically indeterminate quantities, the writer has used the method with entire success, although even such simple cases require careful calculations.

The Application of the Theory of the Continuous Beam in Calculating the Stresses in Frames with Rigid Connections. A frame with rigid connections is one in which all members are connected at

Mr. Slettum.

their intersection points in such a way that the angle between any two members meeting at a point will remain constant under all conditions of loading. A change in the direction of the end tangent of one member, therefore, will cause the same change in the direction of the end tangents of all other members meeting at the point. As this is the basis of the theory of the ordinary continuous beam, it is self-evident that this theory is applicable to such frameworks as described herein.

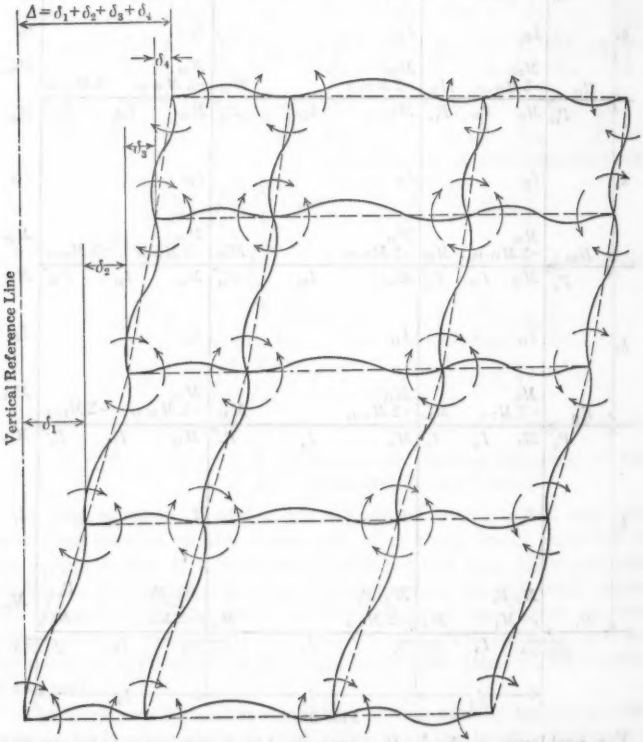

FIG. 32.

To illustrate the general application of the theory of the continuous beam for calculating the stresses in such frames, take the framing bent of a four-story structure, as shown in Fig. 31.

The moments of inertia have been assumed to be different for different members, but constant throughout the length of each separate member. The only difference in the case of a variable moment of

inertia is that the coefficients in the three-moment equation change as shown under the theory of the continuous beam. Mr. Slettum.

The frame will be assumed to be loaded in any manner, horizontally or vertically, by forces acting in its plane.

The influence of axial stresses on the deformation of the frame will be neglected.

$H_I + H_{II} + H_{III} + H_{IV} + H_V$ is the resultant of all horizontal forces, including wind load, concentrated at the different floor levels.

Under the application of external forces, the frame will deflect from its original position. The direction in which it will deflect cannot always be told beforehand. It will be convenient to assume,

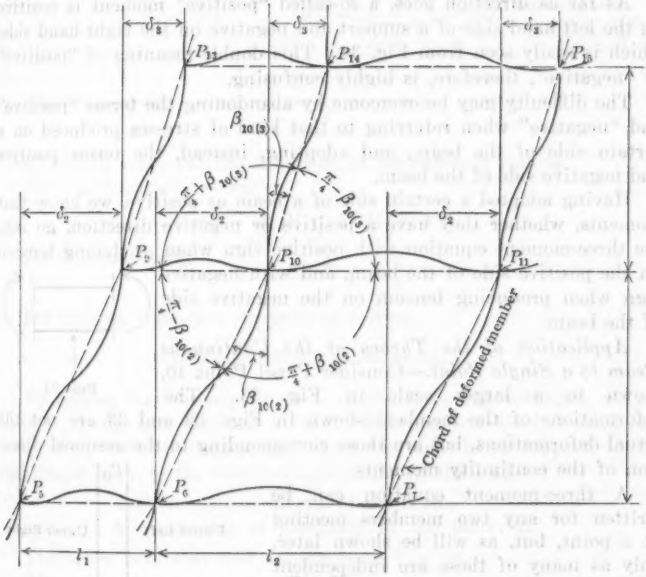

FIG. 33.

therefore, that the frame always deflects in a certain fixed positive direction. By the sign of the figure giving its value we can then tell the actual direction. If it is plus, the frame deflects in the direction assumed; if it is minus, it deflects in the opposite direction. This also applies to the unknown continuity moments.

Assume that from left to right is the positive direction for deflections.

Assume a clockwise direction as positive for moments when applied to the panel points, and counter clockwise when applied to the members.

Mr. Slettum.

In Fig. 32 is shown the deflected frame with the moments applied to the panel points. As each panel point is in equilibrium, the algebraic sum of the moments about any point must equal zero; hence, if all moments but one about a point are assumed to act in a positive direction, this latter moment will equal the sum of the others, and will be negative, as shown in Fig. 32.

When speaking about beams, it is the usual practice to term moments producing tension on the bottom side "positive", and those producing tension on the top side "negative", the reason being that they go into the three-moment equations with positive and negative signs, respectively.

As far as direction goes, a so-called "positive" moment is positive on the left-hand side of a support and negative on the right-hand side, which is easily seen from Fig. 34. This double meaning of "positive" or "negative", therefore, is highly confusing.

The difficulty may be overcome by abandoning the terms "positive" and "negative" when referring to that kind of stresses produced on a certain side of the beam, and adopting, instead, the terms positive and negative side of the beam.

Having adopted a certain side of a beam as positive, we know that moments, whether they have a positive or negative direction, go into the three-moment equation with positive sign when producing tension on the positive side of the beam, and with negative sign when producing tension on the negative side of the beam.

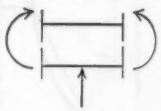

FIG. 34.

Application of the Theory of the Continuous Beam to a Single Point.—Consider Panel Point 10, shown to a larger scale in Fig. 33. The deformations of the members shown in Figs. 32 and 33 are not the actual deformations, but are those corresponding to the assumed direction of the continuity moments.

A three-moment equation can be written for any two members meeting at a point, but, as will be shown later, only as many of these are independent of each other as there are members meeting at the point, less one. Thus, if there are four members meeting at a point, we can write only $4 - 1 = 3$ independent equations.

For convenience, therefore, we shall confine ourselves to members forming either a lower left, upper right, or lower right, corner, as shown in Fig. 35.

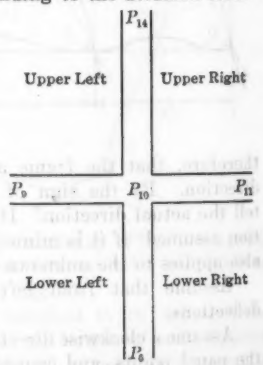

FIG. 35.

Mr. Slettum.

The three-moment equation for the ordinary continuous beam is:

$$M_0 \frac{l_0}{I_0} + 2 M_1 \left(\frac{l_0}{I_0} + \frac{l_1}{I_1} \right) + M_2 \frac{l_1}{I_1}$$

$$= C_0 + C_1 + 6 E \left(\frac{\delta_1 - \delta_0}{l_0} + \frac{\delta_1 - \delta_2}{l_1} \right) \ldots\ldots\ldots (1)$$

The subscript, 0, refers to the left-hand span, and the subscript 1, to the right-hand span. (See Fig. 36.)

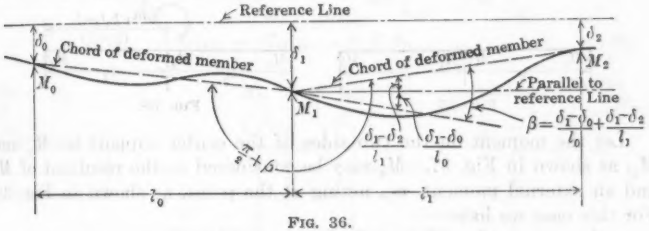

FIG. 36.

C_0 and C_1 represent the influence of the external loading.

For concentrations we have:

$$C = - \Sigma P \frac{l}{I} k l (1 - k^2).$$

For uniform loads:

$$C = - \frac{1}{4} p l^2 \frac{l}{I}.$$

For external moments (or pairs of forces):

$$C = - \Sigma m \frac{l}{I} (3 k^2 - 1).$$

By adding the subscript, 0 or 1, in the foregoing formulas, we get C_0 or C_1, as the case may be. $k l$ is the distance from the left-hand support, in the left-hand span, and from the right-hand support, in the right-hand span, to the point of application of the load.

I = moment of inertia of the beam.

E = modulus of elasticity of the material.

The other notations will appear from Fig. 36.

The external moments, m, go into the equation with positive sign when acting counter clockwise in the left-hand span and clockwise in the right-hand span.

The unknown continuity moments, M_0, M_1, and M_2, are assumed to act in such a direction that they produce tension on the positive side of the beam, which is the under side.

From Fig. 36 it is seen that the angle, β, which represents the change in angle between the two members, equals:

$$\beta = \frac{\delta_1 - \delta_0}{l_0} + \frac{\delta_1 - \delta_2}{l_1} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Mr. Slettum.

Therefore, the three-moment equation (1) can be written:

$$M_0 \frac{l_0}{I_0} + 2\, M_1 \left(\frac{l_0}{I_0} + \frac{l_1}{I_1}\right) + M_2 \frac{l_1}{I_1} = C_0 + C_1 + 6\, E\, \beta \ldots\ldots (3)$$

Now, a frame differs from an ordinary continuous beam therein, that, instead of having the same moment, M_1, on both sides of the center support, it has different moments on the two sides, due to the action of the other members meeting at the point.

FIG. 37.

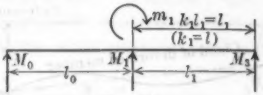

FIG. 38.

Let the moment on the two sides of the center support be M_1 and M_2, as shown in Fig. 37. M_2 may be considered as the resultant of M_1 and an external moment, m_1, acting at the point, as shown in Fig. 38. For this case we have:

$$M_0 \frac{l_0}{I_0} + 2\, M_1 \left(\frac{l_0}{I_0} + \frac{l_1}{I_1}\right) + M_3 \frac{l_1}{I_1} = -m_1 \frac{l_1}{I_1} (3\, k_1{}^2 - 1) + 6\, E\, \beta.$$

But $$k_1 = 1, \text{ and } m_1 \frac{l_1}{I_1} (3\, k_1{}^2 - 1) = 2\, m_1 \frac{l_1}{I_1}.$$

Moving this term to the left side we get:

$$M_0 \frac{l_0}{I_0} + 2\, M_1 \frac{l_0}{I_0} + 2\, (M_1 + m_1) \frac{l_1}{I_1} + M_3 \frac{l_1}{I_1} = 6\, E\, \beta.$$

But $M_1 + m_1 = M_2$, therefore we have, in general, for such cases:

$$M_0 \frac{l_0}{I_0} + 2\, M_1 \frac{l_0}{I_0} + 2\, M_2 \frac{l_1}{I_1} + M_3 \frac{l_1}{I_1} = C_0 + C_1 + 6\, E\, \beta \ldots\ldots (4)$$

This is the three-moment equation as applied to frameworks.

From Equation (2) we see that β is positive when the angle between the chords of the deformed members measured on the positive side of the beam is increased, and negative when the same angle is decreased.

Choosing the under side of $P_9\, P_{10}$ as the positive side, we have (see Fig. 39 and also Fig. 33):

For "lower left":

$$\Sigma\, M_{17\text{-}18} \frac{l_1}{I_{15}} + 2\, M_{20} \frac{l_1}{I_{15}} - 2\, M_{19} \frac{h_2}{I_{12}} + M_{11} \frac{h_2}{I_{12}} = C_{15\,(9)} + C_{12\,(6)} - 6\, E\, \beta_{10\,(2)} \ldots\ldots\ldots\ldots\ldots (5)$$

For "upper left":

$$\Sigma\, M_{17\text{-}18} \frac{l_1}{I_{15}} + 2\, M_{20} \frac{l_1}{I_{15}} - 2\, M_{21} \frac{h_3}{I_{19}} + M_{29} \frac{h_3}{I_{19}} = C_{15\,(9)} + C_{19\,(14)} - 6\, E\, \beta_{10\,(3)} \ldots\ldots\ldots\ldots\ldots (6)$$

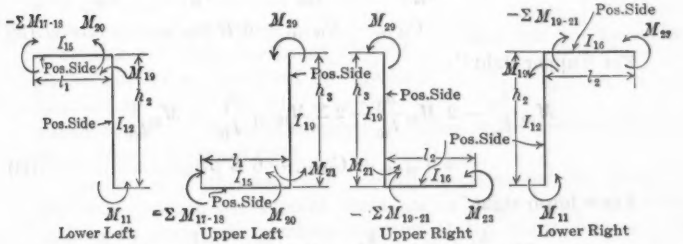
Mr. Slettum.

For "upper right":

$$M_{29}\frac{h_3}{I_{19}} - 2\,M_{21}\frac{h_3}{I_{19}} - 2\,\Sigma\,M_{19\text{-}21}\frac{l_2}{I_{16}} - M_{23}\frac{l_2}{I_{16}} = C_{19\,(14)} + C_{16\,(11)} - 6\,E\,\beta_{10\,(3)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

For "lower right":

$$M_{11}\frac{h_2}{I_{12}} - 2\,M_{19}\frac{h_2}{I_{12}} - 2\,\Sigma\,M_{19\text{-}21}\frac{l_2}{I_{16}} - M_{23}\frac{l_2}{I_{16}} = C_{12\,(6)} + C_{16\,(11)} - 6\,E\,\beta_{10\,(2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (8)$$



Note that in these sketches the moments are shown applied to the members, and not to the panel points.

FIG. 39.

In these equations the first subscript for C refers to the member, and the second subscript, which is in parentheses, refers to the panel point for which C is to be figured. In the same way, the first subscript for β refers to the panel point, and the second subscript to the story of the frame. (See Fig. 33.)

From Fig. 40 it is seen that the positive side of the members in one panel is the inside, and in the next panel the outside, the inside of one panel being the outside of its neighbor. It would be necessary, therefore, to assume the positive side of one member and then go through the whole frame and mark the positive side, as shown in Fig. 40.

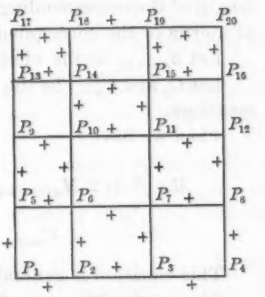


FIG. 40.

This would be very likely to cause some confusion, but the difficulty can be overcome simply by changing the signs throughout in the equations for "upper left" and "lower right". It is easily seen that this is equivalent to changing the positive side in "upper left" and "lower right", so that the inside of the panel to which the two members

Mr. Slettum.

belong, in all cases, will be the positive side. The resulting equations for the point, P_{10}, therefore, are:

For "lower left":

$$\Sigma M_{17-18}\frac{l_1}{I_{15}} + 2M_{20}\frac{l_1}{I_{15}} - 2M_{19}\frac{h_2}{I_{12}} + M_{11}\frac{h_2}{I_{12}} = C_{15\,(9)} + C_{12\,(6)} - 6E\beta_{10\,(2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

For "upper left":

$$-\Sigma M_{17-18}\frac{l_1}{I_{15}} - 2M_{20}\frac{l_1}{I_{15}} + 2M_{21}\frac{h_3}{I_{19}} - M_{29}\frac{h_3}{I_{19}} = -C_{15\,(9)} - C_{19\,(14)} + 6E\beta_{10\,(3)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

For "upper right":

$$M_{29}\frac{h_3}{I_{19}} - 2M_{21}\frac{h_3}{I_{10}} - 2\Sigma M_{19-21}\frac{l_2}{I_{16}} - M_{23}\frac{l_2}{I_{16}} = C_{19\,(14)} + C_{16\,(11)} - 6E\beta_{10\,(3)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

For "lower right":

$$-M_{11}\frac{h_2}{I_{12}} + 2M_{19}\frac{h_2}{I_{12}} + 2\Sigma M_{19-21}\frac{l_2}{I_{16}} + M_{23}\frac{l_2}{I_{16}} = -C_{12\,(6)} - C_{16\,(11)} + 6E\beta_{10\,(2)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

As the rule of signs now is the same for all panels, the positive sign always being the inside of the panel, we can write the following general equation: Let P_n, P_{n+1}, and P_{n+2} be the consecutive supports from left to right of any two members of a frame forming a lower left, upper left, upper right, or lower right corner. Let M_n, $M_{n+1\text{ left}}$, $M_{n+1\text{ right}}$, and M_{n+2} be the corresponding moments. Let l_m and l_{m+1} be the length of the corresponding members. Let I_m and I_{m+1} be the moments of inertia of the corresponding members.

Let $\beta_{n+1\,(r)}$ be the change in angle between the two members.

Let C_n and C_{n+1} be the influence of external load on the corresponding members.

Then we have:

$$M_n\frac{l_m}{I_m} + 2M_{n+1\text{ left}}\frac{l_m}{I_m} + 2M_{n+1\text{ right}}\frac{l_{m+1}}{I_{m+1}} + M_{n+2}\frac{l_{m+1}}{I_{m+1}} = C_{m\,(n)} + C_{m+1\,(n+2)} + 6E\beta_{n+1\,(r)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (13)$$

This equation is general, and the rule of signs is as follows:

The continuity moments, M_n, M_{n+1}, etc., enter with positive sign when producing tension on the positive side of the member, that

Mr. Slettum.

is, the inside of the panel to which the member belongs. The quantities, C_m and C_{m+1}, enter with positive sign when the external loads act in such a way as to produce tension on the negative side of the member, that is, the outside of the panel to which the member belongs.

The quantity, $\beta_{n+1\,(r)}$, is positive when the angle between the two members, measured on the inside of the panel to which the two members belong, becomes greater; or, in short, follows the same rule as for the ordinary continuous beam.

To make the case absolutely clear, the positive sides of members and the sign for β have been shown in Fig. 41. The sign for β assumes that the frame is supposed to deflect in the positive direction, that is, from left toward right.

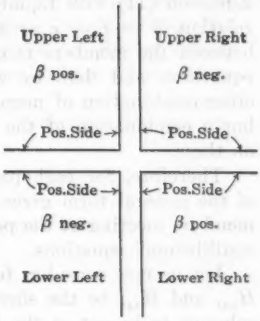

FIG. 41.

Number of Unknowns and Equations Required to Solve the Problem.—At each panel point there are as many unknown bending moments as there are members meeting at the point, less one, this latter being equal to the algebraic sum of the others and opposite in direction.

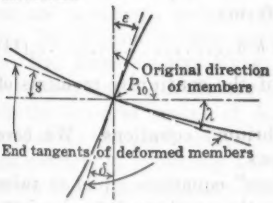

FIG. 42.

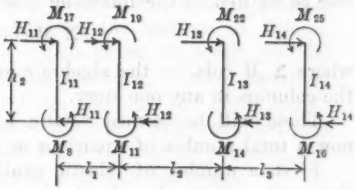

FIG. 43.

Besides, we have an unknown deflection, $\delta = \beta h$, for each story of the frame.

This gives a total number of unknowns equal to twice the number of members in the frame, less the number of panel points, plus the number of stories.

As already stated, we can write a three-moment equation for any combination of two members meeting at a point. However, only three —or in general the number of members meeting at a point, less one— are independent of each other.

To illustrate this, let us again consider the point, P_{10}. Equation (9) expresses the relation, $\delta = j$ (see Fig. 42); Equation (10) expresses the relation, $j = \epsilon$; and a combination of the two will express the relation, $\delta = j = \epsilon$.

Mr. Slettum.

Equation (11) expresses the relation $\epsilon = \lambda$. A combination of Equation (11) with Equations (9) and (10), therefore, will express the relation, $\delta = j = \epsilon = \lambda$. Thus it is seen that the elastic relation between the members meeting at a point is fully expressed by three equations, and that, by writing the three-moment equation for any other combination of members, we write an equation which is nothing but a combination of the three equations, and accordingly dependent on these.

Therefore, for each panel point, we have a number of equations, of the general form given by Equation (13), equal to the number of members meeting at the point, less one. These will be termed "elastic equilibrium" equations.

Let us now consider, for example, the second story. Let H_{11}, H_{12}, H_{13}, and H_{14}, be the shears in the respective columns. Assume the columns to be cut at the floor levels, and the internal forces applied, as shown in Fig. 43.

As the system of forces is in equilibrium, we have:

$$\begin{aligned} M_8 + M_{11} + M_{14} + M_{16} + M_{17} + M_{19} + M_{22} + M_{25} \\ = h_2 (H_{11} + H_{12} + H_{13} + H_{14}) \\ = h_2 (H_V + H_{IV} + H_{III}) = h_2 \delta_{II}, \end{aligned}$$

where δ_{II} is the external shear in the story.

Similar equations can be written for each story. These equations can be written in the following general form:

$$\Sigma M \text{ cols.} = h \delta \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

where ΣM cols. = the algebraic sum of the continuity moments of the columns in any one story.

These will be termed "static equilibrium" equations. We have now a total number of equations as follows:

First, a number of "elastic equilibrium" equations equal to twice the number of members in the frame, less the number of panel points; and second, a number of "static equilibrium" equations equal to the number of stories in the frame. The total number of equations, therefore, equals twice the number of members in the frame, less the number of panel points, plus the number of stories, which is the number required to solve the problem.

Solution of the Problem.—Considerable time can be saved by following always a certain method in solving problems of this nature. The following is proposed:

(*a*) Make sketches of the structure, and show the quantities, as in Figs. 31 and 32. In Fig. 32 it is not necessary to show the deformed members themselves, but only their chords.

(*b*) Tabulate the values of l, h, I, $\frac{l}{I}$, $\frac{h}{I}$, and C.

(*c*) Write the equations with coefficients for the unknowns and the constants given by letters. For each story write the equation containing the term $6\,E\,\beta$ by itself, and in the other equations containing that term, substitute its value, as given by this equation. Arrange the unknowns in numerical order, and place all constants on the right-hand side of the equation. Mr. Slettum.

(*d*) Tabulate the numerical values of the coefficients for the unknowns and of the constants.

(*e*) Eliminate the unknowns.

(*f*) Find the unknowns by substitution.

The deflections are calculated from the general formula:

$$\delta = \beta h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

where δ = deflection of any single story.

The total deflection of the frame is:

$$\Delta = \Sigma\,\delta = \Sigma\,\beta\,h \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

After the continuity moments have been calculated, each member may be assumed to be cut and freely supported at the panel points, and loaded with the external loads and the continuity moments. The further calculation is then as for an ordinary beam on two supports.

L. R. Ash,* M. Am. Soc. C. E. (by letter).—There are few cities in the United States where the freight-house and manufacturing districts are so sharply isolated from the business center as in Kansas City. In addition to this division between the sections of Kansas City, Mo., Kansas City, Kans., with a population of nearly 100 000 and its large and varied manufacturing interests, is also separated from the business center of Kansas City, Mo., by the bluffs which extend along the north and west sides of the city. The traffic between these districts is extremely heavy and, for a number of years, it has been seriously handicapped by bad grades and indirect routes. Mr. Ash.

The apparent need of a trafficway between Kansas City, Mo., and Kansas City, Kans., and to the West Bottoms, was great enough to enlist private capital in the enterprise of building the Sixth Street or Inter-city Viaduct some 8 or 10 years ago. This structure was built as a toll viaduct, and although it has proved to be a failure, from a financial standpoint, this failure in no way indicates that such a structure was not needed, but demonstrates the reluctance of the American public to pay tolls. During the times that the Inter-city Viaduct was open for traffic without charge, the structure was crowded with travel, both to and from Kansas City, Kans., as well as to and from the West Bottoms.

The question of building a viaduct at 12th Street, connecting with the West Bottoms, has been discussed for the last 15 years, and

* Kansas City, Mo.

Mr. Ash. although every one realized its great need, it seemed almost impossible to harmonize the various interests which in one way or another were affected by the building of the structure. The old viaduct at 12th Street provided only for street-railway traffic. All vehicular traffic between the West Bottoms and Kansas City, Kans., and the business center of Kansas City, Mo., had no thoroughfare from 6th Street on the north to 24th Street on the south, a distance of more than 1½ miles. When, in addition to this, we consider the fact that neither Sixth Street nor 24th Street led in the direction of the terminus for this large traffic, we see more clearly the great need of a trafficway leading to the heart of the business portion of the city.

Numerous meetings were held with representatives of the various organizations, such as the Team Holders Association, Real Estate Board, Commercial Club, etc., in an attempt to determine the most practicable structure, both as regards the requirements of traffic and the elimination of damages. These discussions were frequently very acrimonious, and politics cut no small figure in the handling of the proposition. The management of the whole enterprise was a shining example of the need of a more responsible and centralized authority in municipal affairs.

One of the great problems which confronted the promoters of the 12th Street Viaduct was that of grades. About 5% seemed to be the only practicable grade on 12th Street, and, in the minds of a great many people, this grade was prohibitive when heavy vehicular traffic was considered. The grade, as originally established, was 5.09%, and this would have necessitated a cut of about 17 ft. at the top of the hill, which would have resulted in a very heavy property damage estimated at about $250 000. This matter came up while the writer was City Engineer of Kansas City, Mo., and he suggested the elimination of this property damage by raising the grade to within about 4 ft. of the established grade at Washington Street. This increased the viaduct grade to 5.52%, a very slight change from the old one; and the opposition to the structure, thus avoided, abundantly justified the change.

The advent of the motor truck has decreased the necessity for lower grades, except where reasonably attainable, but, as a concession to the demand for a low-grade trafficway between the Bottoms and the business section, a lower deck was provided on the viaduct with a maximum grade of about 2½ per cent. It is expected to utilize this portion of the viaduct by building roadways along the bluff leading to the north and to the south from the east end of this lower deck. In the writer's opinion, the building of these roadways will not be justified, as they will lead to the old trafficway at 6th Street on the north, or to 17th Street on the south, neither of which points is in the line of travel, and from which there will be bad grades and other

conditions not inviting to heavy vehicular traffic. It would seem that a better solution of the problem would be to tunnel from the east end of the lower deck to about 14th and Wyandotte Streets, thus insuring a very easy grade and a direct route for the distribution of the traffic from the West Bottoms. Mr. Ash.

Now that the structure has been completed and thrown open to the public, the great need of it is proved by the very great traffic, both vehicular and by street cars, using it; and this is drawn to the structure in spite of the fact that the approaches to the viaduct have not been paved, as they await the settlement of the embankments at each end. The structure saves several minutes to each of the many people who go each day from the eastern portion of the city to the West Bottoms, and the 5.52% grade has proved to be no serious handicap, either to motor or horse-drawn vehicles.

It is interesting to note that the building of the viaduct has resulted in enhancing real estate values and rentals on East 12th Street and the adjacent streets for a distance of 3 or 4 miles eastward from the structure. This is because the opening of 12th Street provides a direct way to the West Bottoms for the large number of people employed there, without having to transfer or travel several blocks out of their way. The 12th Street cars, although greatly increased in number, are crowded with passengers, and the building of the viaduct has fixed 12th Street as the principal east and west artery of the city.

Mr. Howard has gone very fully into the design and construction features, and there is no additional comment to be made except to remark on the very satisfactory result, as shown by the finished structure. The surface finish of the concrete is not all that could be desired, but it is believed that it is in keeping with the character of the structure and, when conditions in the neighborhood are considered, it is thought that the more expensive methods of treating concrete surfaces would not have been justified in this case.

The specifications as drawn would permit the engineer to require the contractor to put a cement-gun surface on all columns and cantilevers, as well as on the outside surfaces of the longitudinal girders, but, in the writer's opinion, the attempt to place this finish on surfaces of the character in this structure, would not result satisfactorily, and it is believed that the surface as produced by the forms, with the rough places smoothed off with hammer and chisel and in certain places filled with mortar, has been the best treatment practicable.

The treatment of concrete surfaces is receiving a great deal of attention, and various methods have been advanced for producing a surface which is smooth and, at the same time, does not present the expressionless effect of a smooth mortar surface. The writer believes

Mr. Ash. that specifications can most easily provide for the finish of concrete surfaces by requiring the bidders to tender on two or three different kinds of treatment at a stated price per unit of surface, leaving the engineer to choose that method which, in his opinion, most nearly suits the condition when the forms are removed. Of course, all specifications should require forms to be built of smooth lumber, with tight joints and true to line.

The character of surface desired should be determined by the general characteristics of the structure, its location, type of construction, etc. No attempt should be made to give the concrete the appearance of stone or other material, and it is thought that, with a few exceptions, a reasonably smooth surface which is produced by good forms and well-spaded concrete, is better than can be secured by special treatments.

On the 12th Street Viaduct 22 ft. of the upper deck is set aside for street-car tracks, and a roadway, 30 ft. wide on the south side, is left for vehicles, a sidewalk 5 ft. wide extending along the south side of the structure. Although this arrangement has some advantages over that of placing the street railway in the center of the roadway, it would seem that the space between the hand-rails would be used more efficiently with the tracks in the center, as is the case in an ordinary city street. About the only justification for placing the tracks in a space independent of the roadway, is the length of the structure and the grade. It is believed that a sidewalk, 8 ft. wide, and a clear roadway of about 50 ft. between the curbs, with street-railway tracks in the center, would have resulted in a structure which would have cost somewhat less and would have been better suited to the general traffic conditions. As it is, vehicles on the north side of 12th Street, at each end of the viaduct, must cross the street railway tracks.

The use of wood blocks for paving the roadway portion has proved entirely satisfactory. It was feared that the grade would cause the pavement to be slippery, but the blocks were laid with a lath between each row, and the remaining space was well filled with broken stone. The blocks are 3 in. wide, and the resulting surface undoubtedly provides a better footing for horses than stone block, asphalt, or brick. The writer has observed heavily loaded teams turning out of the street railway portions of certain streets where there is stone block pavement, to the wood block pavement at the sides, because of the better footing secured on the latter.

The laying of the wood blocks on the viaduct without a sand cushion has been entirely satisfactory, and demonstrates the wisdom of omitting one of the great sources of trouble with pavements of this type. With care in finishing the concrete base, the surface can

be brought to true crown and grade without serious trouble, and when this is done there is no justification whatever for the use of a sand cushion. Mr. Ash.

The structure represents a great amount of careful study of the architectural treatment as well as the engineering features, and it is becoming more and more apparent that engineers should give consideration to matters pertaining to the appearance of structures of this character. There seems to be little excuse for absolutely neglecting the esthetic treatment of engineering structures, and although the Profession has been prone to do this, it is gratifying to note a marked change in its attitude in this matter.

JOHN LYLE HARRINGTON,* M. AM. SOC. C. E. (by letter).—So much of the Twelfth Street Trafficway Viaduct is of usual construction, and the author has exposed so fully the elements which are of interest to the engineer who is thoroughly experienced in the design of reinforced-concrete structures, that few matters pertaining to the viaduct require further comment. Mr. Harrington.

Some designers of reinforced-concrete structures consider the work so simple that their plans consist of a few general drawings showing principal dimensions, the number, size, and approximate position of reinforcing bars, and with a few notes pertaining to ties, constituents of concrete, and character of finish; and their specifications consist of little more than references to standard specifications for materials, a brief description of the structure, and the clauses relating to bids. Those of another class, generally of European training, go to the opposite extreme, and make extremely full plans and all the detailed calculations necessary for the exact determination of the stresses in continuously-framed structures, composed of uniformly perfect materials, moulded and placed exactly in accord with the plans. Both are in error. Ill-considered, carelessly-made plans and loosely-drawn specifications are responsible for a large number of defective structures and for many costly failures. Lax supervision is almost sure to follow such designing; and, if the engineer has such small regard for thorough work, the contractor and his foremen and workmen surely cannot be expected to give the construction the greater thought and care essential to satisfactory workmanship.

On the other hand, the extremist who bases his plans on the expectation of perfect materials and workmanship, and allows nothing for imperfections in both, produces designs which, though carried out with all reasonable care, cannot secure satisfactory results. At the same time, he wastes much labor in substantially useless calculation, for considerations of convenience and of uniformity of design do not permit of sectioning exactly in accord with the calculated stresses,

* Kansas City, Mo.

Mr. Harrington.

and knowledge of the imperfections of materials, of the shortcomings of workmen, and of the difficulties of construction, leads to the making of many assumptions and approximations.

Competent and experienced designers, who know and respect the theories involved in the design, but who also give careful consideration to the imperfections of the materials and the practical difficulties of construction, will secure the satisfactory and enduring structures. Mathematical analysis must be supported by sound judgment.

The advocates of the use of high-carbon steel for reinforcing concrete rarely understand its fragility. Any engineer who has had much experience in the shops knows that even medium steel, when dropped from the skids or otherwise roughly handled, is likely to be fractured; and in many instances which have come to the writer's attention, the breakage of high-carbon steel bars in unloading and handling has been so great as to cause serious doubt as to their quality. The bending of reinforcing bars is not a nice job: It is done in haste, and generally by unskilled workmen, often with unsuitable tools; hence breakage, or what is worse, incipient cracks, which escape notice but enlarge under stress in the structure, is sure to result from the use of this fragile material.

In the writer's opinion, the saving in cost resulting from the use of high-carbon steel does not warrant its adoption. The saving is generally estimated to be proportional to the difference between the unit stresses permissible in the various grades of steel, but this is not true, for, as every experienced designer knows, members cannot be proportioned exactly in accord with the stresses in them, and a large quantity of ties, hoops, and spacers are necessary, regardless of the unit stresses used. The saving is not worth the risk, particularly in structures subject to moving loads.

The finish of concrete structures is one of the most serious moot questions relating to them. In choosing a finish, the improvement in appearance is but one of the considerations; the added cost, the greater absorption of water, and the fouling by smoke resulting from the breaking of the cement skin, must be carefully considered. If the structure is situated so that few will see it at close range, or that it will be blackened by smoke, the expense of treating the surface is not warranted. The writer recently examined a viaduct over a railway yard, and it was covered with soot to such an extent that neither the character of the surface nor the material of the structure could be readily determined. In parks, on boulevards, and in other exposed positions, however, where many view the structure daily, bush-hammering, rubbing, floating, or some other satisfactory method of finishing the surface should be used in order to remove ugly form marks and secure uniformity of color and texture. There should be

Mr. Harrington.

no attempt to make concrete resemble stone, but flat surfaces should be broken. Plastering is almost certain to scale off and leave a surface uglier than that left by the forms; and, except possibly by using steel-lined forms, it is practically impossible to secure satisfactory surfaces, except by some mechanical treatment.

No amount of surface dressing, however, will compensate for ugly lines and details, and the use of brick, tile, or plaster ornaments is rarely if ever commendable. The designer of such structures as this must rely for appearances chiefly on his ability to give them form and line suitable to the service to be rendered by the structure and in harmony with its dimensions and surroundings. The selection of the central or distinguishing features and the general treatment of the principal forms and parts of the structure are of vastly more importance than ornamentation or finish of surface.

The writer had too large a part in the design and construction of this viaduct to permit him to extol its appearance. The situation and conditions were unusually difficult, hence careful study was required to secure such esthetic results as the general views of the viaduct disclose.

Mr. Howard.

E. E. HOWARD,* M. AM. SOC. C. E. (by letter).—It is of interest to observe that the mathematical demonstrations by Mr. Mensch and Mr. Slettum alike warrant the conclusion that the approximate methods by which the columns were actually proportioned give results within safe limits. There are refinements beyond which ordinary designing calculations for elastic structures need not be carried, provided there are occasional demonstrations that the approximate methods will vary only within safe limits. The type of arch and abutments suggested by Mr. Mensch has been considered and analyzed for similar cases, although not for this specific one, and the additional material in the arch proper to provide for the greater stresses, the adjustment for foundations, etc., never seemed to be compensated for by the saving in abutments. The foundation difficulty referred to may easily become quite serious.

To answer Mr. Mensch regarding high-carbon steel, the writer can suggest only that the same conservatism which leads most engineers to use medium steel in structures wholly of steel, would prompt the use of the same material in structures partly of steel. The writer has seen high-carbon steel bars, actually by the carload, which had been inspected and accepted at the mill, broken by merely being thrown from the car in unloading. Evidently, the sentence concerning the fastening of bars was not wholly clear, for the bars were tied together principally to hold them in correct position while placing the concrete. Any joining of bars intended to transmit the load from one bar to

* Kansas City, Mo.

Mr. Howard.

another was made by some definite splice, such, for instance, as bolted rope clips.

Mr. Holmes' suggestions for constructing influence lines for extreme fiber stress brings forward another of the frequent cases in which individual preference may enter. In this special instance, the designers felt that to carry out the equations another step and plat the influence in lines of extreme fibers would require more work than the method followed. It is easy to agree with Mr. Holmes that in certain cases the other method would be most desirable.

The writer is most heartily in accord with Mr. Holmes' views concerning the relations between engineers, contractors, and public officials. The absurd and ridiculous laws sometimes controlling public construction have been cause for exasperation to many engineers, although, after all, the rabbit-like timidity of public officials, in fearing to do what they believe to be right, may be equally at fault. Although supposedly representing a whole community, public officials are often prone to listen to the vociferous requirements and the threats or promises of a small group of those who have personal interests to promote, and to forget the great silent majority who are not present. Fortunately, there are occasional very refreshing exceptions.

Mr. Upson's figures concerning the piles are substantially correct, but, as a just concession to the increased percentage of overhead cost due to the reduced quantities, a payment of $2 462 was made to the Contractor. This still left the City about $20 000 ahead of the probable cost of pre-cast piles. The Raymond piles were well suited to the foundation conditions and to the season in which the work had to be done.

The rather unusual requirements of a cement-gun finish, referred to by Mr. Ash, were included as one alternative method of surface finish only after the manufacturers of the cement-gun equipment gave assurances that they could provide such work, and gave an approximate price for it. The experiences of other users of the cement gun, especially on viaducts of the Kansas City Terminal Company, cast serious doubt on the practicability of producing an even, uniform, $\frac{1}{8}$-in. mortar coat over irregular surfaces. It was evident that the extruding corners would not be coated at all, that re-entrant corners and moulds would be filled and rounded, and that the clean lines of the structure would be lost. It is the writer's opinion that the cheap and satisfactory surface finish for ordinary concrete will some day be supplied by some kind of lime-cement wash or paint which can be brushed on, which will have characteristics so similar to the concrete that it will not flake off. Many industrial chemists are studying cements, limes, and mortars, and such a wash should be available at no distant day.

In conclusion, it has been a pleasure to the writer on frequent occasions to hear expressions of pride and satisfaction, from residents

Mr. Howard.

of Kansas City, who provided the money for the viaduct, in the pleasing appearance and evident excellency of construction. The public verdict is that the structure is a success. The old excuse that engineers have been prone to bring forward, that their principals would not provide money for beautiful structures and therefore such structures were ugly, belonged to pioneer conditions, and, as Mr. Green suggests, the United States may fairly be said to have passed that stage. It would be hard to find any one, even of those who paid special assessments for this viaduct, who would ask the return of the small additional percentage which it cost, over the expense of a series of posts and beams which would have carried the load. If the Engineering Profession will lead the way for substantial and beautiful bridges, public sentiment will follow fast enough.

The writer desires to express his cordial appreciation for the courteous words of approval of his paper by those who discussed it; and, on behalf of all the engineers connected with the design and construction of the Twelfth Street Trafficway Viaduct, for their compliments in regard to the structure.

Paper No. 1358

THE AUTOMATIC VOLUMETER*

By E. G. Hopson, M. Am. Soc. C. E.

With Discussion by Messrs. George W. Booth and E. G. Hopson.

Synopsis.

This paper describes an apparatus intended to gauge the flow of fluids by the collection of a proportionate part of the flow, or its equivalent, in a small vessel where it can be readily measured at any time. This result is accomplished by the use of very small orifices for the purpose of regulating the discharge into or out of the collecting vessel, and other special arrangements, whereby the pressure head under which the discharge into the collecting vessel takes place is at all times the equivalent, or a constant ratio, of the velocity head of the liquid or gas being measured.

Practically all measurements of flow of fluids on a large scale are difficult and expensive. As soon as one gets beyond the small service meter for water or gas, very expensive apparatus is generally involved. The accuracy of any apparatus with moving parts or mechanism is, moreover, frequently open to question, due to the difficulty of constructing any such mechanical device with a constant coefficient of

* Presented at the meeting of December 1st, 1915.

flow. To express the latter point in other words, the usual mechanical meter does not record with equal precision at different rates of flow; thus an instrument that will record correctly at a given rate will usually record too small for lesser rates, and *vice versa*.

The importance of a cheap and reliable apparatus to record the flow of water in small irrigation laterals, for individual services, induced the writer to take up the study of developing this device. The result indicates that it may be of equal utility to city water-works systems or to industrial plants, particularly where it is desired to ascertain the duty of pumping machinery, or to determine the use or waste of water in a pipe-distributing system. Its application to all forms of flow measurement necessarily follows as a matter of course; thus, if it can be used for water, it is equally available for oil, solutions of various kinds, or even for gas or steam. All fluid flow is subject to the same law that governs velocity and its relation to head, so that the application, to any fluid, of a device dependent on this factor only is a matter of detail.

In this discussion no attempt is made to describe the application of the device for other purposes than the measurement of the flow of water, and the experiments and tests herein described only have reference to water flow and measurement thereof.

The law now requires that on Government irrigation projects payment for maintenance shall be based on measured quantities of water delivered to the individual. Under present conditions, it is practically impossible to determine quantities; only a rough guess, in which one is guided to some extent by the ditch rider's observation and notes, is possible.

For irrigation use, probably one of the most dependable devices for measuring individual service is the Dethridge meter, which is merely a paddle-wheel operating a recording counter and has the advantage of actually measuring the displacement by each revolution of the wheel. Other methods of measurement, by weirs and modules, are inaccurate, save with apparatus and attention entirely prohibitive for ordinary purposes. The Venturi meter, as recently adapted for irrigation use, appears to be the best instrument on the market, so far as scientific accuracy and freedom from accidental interruptions are concerned; but it involves elaborate recording mechanism, with detailed reduction of results, and is expensive.

The volumeter herein described operates by the velocity head of the fluid which is being measured. The velocity head is communicated by a pipe leading from the fluid being measured to the volumeter. Not only is velocity head communicated, but a very small proportion of the actual flow is diverted by this pipe into the apparatus. This proportion is so small, however, and the velocity of flow in the pipe is so insignificant, that there are no appreciable losses of head by friction in the pipe to disturb the basic plan of operation by velocity head. A return pipe from the volumeter to the stream carries away the surplus liquid created by the influent flow.

So far as the volumeter is concerned, it operates by head or pressure. It will operate under the influence of any head or pressure, no matter how derived. Although it has been termed a volumeter—inasmuch as it measures volume—it actually is a velocity meter or pressure meter, in the sense that velocity, or pressure due to velocity, is its operating force. Therefore, it is absolutely essential to its successful operation that it shall be erected in such a way as to be subject to operation by the head due to velocity alone.

The apparatus may be attached to a pipe or conduit, with communication through a Pitot tube, or at submerged orifices, or on a short pipe or box flume of varying cross-section, or at an angle or bend in a pipe or conduit, all as illustrated on Fig. 9. Other methods of attachment will doubtless occur to the reader. The methods, however, are unimportant, so far as the operation of the device is affected, so long as they are consistent and such that the head communicated to the volumeter is a constant factor of the velocity head. The latter is the essential condition.

The most difficult feature of the apparatus to work out was an arrangement whereby the head, under which the interior jet operates, is kept identical with, or is a constant factor of, the velocity head of the stream. It is necessary for the apparatus to be absolutely automatic, and its response to the most minute changes of head to be immediate and of the most delicate sensitiveness. This requirement has been met. The influent entering the upper part of the lower vessel (Fig. 1) creates a pressure at its point of entry equal to the sum of the static and velocity heads of the entering water, the frictional losses in the influent pipe and orifice being negligible, due to their great size and the very low velocities in them. The lighter

medium (liquid or gas) contained in the lower vessel is thus put under pressure. The upper vessel is connected with the flowing water in such manner that only the static head is communicated to it. The flow through the small orifice connecting the two vessels is, therefore, for all practical purposes, that due to the velocity head, or a constant factor of the velocity head, only.

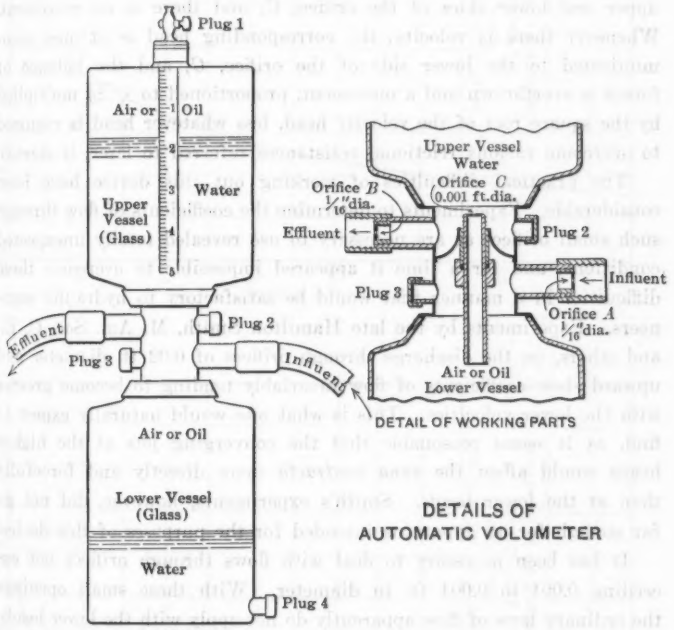

FIG. 1.

The operating details will be fully understood by reference to the detailed drawing, Fig. 1. The influent enters the lower vessel or container at its upper part through an orifice at *A*. The pressure communicated is due to the static head or pressure of the water being measured plus the velocity head due to the rate of flow. This pressure is communicated to the medium (air, oil, or whatever may be used) in the lower vessel, and in turn is transmitted through the

medium to the lower side of the point of connection with the upper vessel at the orifice, *C*.

The water in the effluent pipe is only under the pressure due to the static head of the stream being measured. This pressure is communicated directly through the water in the lower part of the upper vessel down to the upper side of the orifice, *C*. When there is no velocity, the static head of the stream is communicated to both the upper and lower sides of the orifice, *C*, and there is no movement. Whenever there is velocity, the corresponding head is at once communicated to the lower side of the orifice, *C*, and the balance of forces is overthrown and a movement, proportioned to $\sqrt{2g}$ multiplied by the square root of the velocity head, less whatever head is required to overcome various frictional resistances referred to later, is started.

The practical difficulties of working out this device have been considerable. Experiments to determine the coefficients of flow through such small orifices as are necessary to use revealed totally unexpected conditions, and for a time it appeared impossible to overcome these difficulties in a manner that would be satisfactory to hydraulic engineers. Experiments by the late Hamilton Smith, M. Am. Soc. C. E., and others, on the discharge through orifices of 0.02 ft. diameter and upward show coefficients of flow invariably tending to become greater with the lower velocities. This is what one would naturally expect to find, as it seems reasonable that the converging jets at the higher heads would affect the *vena contracta* more directly and forcefully than at the lower heads. Smith's experiments, however, did not go far enough for an apparatus intended for the purposes of this device.

It has been necessary to deal with flows through orifices not exceeding 0.001 to 0.004 ft. in diameter. With these small openings the ordinary laws of flow apparently do not apply with the lower heads, as can be seen by reference to the curves of coefficients, Figs. 2 to 6.

Another marked difference between results obtained with these small orifices and with the larger ones is that apparently the former have distinctly greater coefficients under certain heads than the latter. The largest coefficient noted in Smith's experiments with small orifices was about 66% of the theoretical velocity, and 90% appears to be the rule for the minute orifices referred to herein when operating under heads larger than about 0.2 ft. This is an interesting scientific fact, hard to explain, but it does not seem to be open to question.

FIG. 5.

The curve of coefficients, Fig. 6, shows the coefficients of discharge of some of the orifices experimented on by Smith as compared with those referred to herein, and of which the largest is only about one twenty-fifth part of the size of the smallest of those used by Smith. This curve shows clearly that although the increase in coefficients of flow between the Smith orifices and these small ones is very marked,

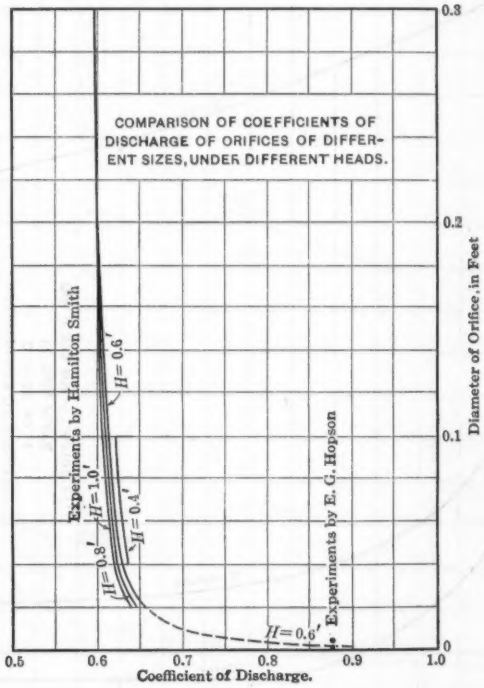

FIG. 6.

a large increase was nevertheless indicated by the sharp rise in Smith's coefficients for his smaller orifices of less than 0.2 ft. diameter.

In the conduct of experiments necessary to determine the coefficients of discharge, the diameters of orifices used were very carefully calibrated by using tapering needle points of which the diameters at different points in their length had been determined by micrometer measurements. Orifices were at first made in a brass plate, $\frac{3}{16}$-in. thick,

and, for the purpose of reducing contraction to a minimum, the up-stream approach was turned—in the thickness of the metal—to an easy curve, so that the orifice itself would be in the position of the *vena contracta*, as nearly as could be determined.

In the determination of flow coefficients for these small orifices, a specially constructed apparatus was used. Water from above and below the orifice being tested was brought to two vertical glass gauge tubes, arranged side by side. The difference in level of the meniscus in each of these tubes was observed by a sliding gauge carrying a cross-hair and working on a vertical scale. In this way the difference in head could be read to less than one-thousandth of a foot. The quantity passing the orifice under a given head was carefully measured in glass graduates. These experiments were repeated a great number of times for different heads. Usually, the run lasted about an hour each time. The results were platted on cross-section paper, and the curves appearing in the various diagrams have been drawn on the basis of these tests, which, for simplicity, were omitted in the final draft.

Four different orifices were experimented with, as follows:

Orifice No. 1.—In $\frac{3}{16}$-in. plate; orifice 0.325 mm. or 0.00107 ft. diameter; up stream with curved approach.

Orifice No. 2.—Same as above, but with diameter of orifice 0.63 mm. or 0.00207 ft.

Orifice No. 3.—Same as above, but with diameter 1.195 mm. or 0.00392 ft.

Orifice No. 4.—In thin sheet metal; diameter 0.323 mm. or 0.00106 ft.

By reference to the curves of coefficients it will be found that for Orifices Nos. 2 and 3, with heads greater than 0.15 ft., the coefficients of flow ranged usually a little less than 90. With Orifice No. 1, the coefficients seemed to be appreciably less, but with Orifice No. 4, of practically the same diameter as No. 1, the only difference being that it is in thin plate, a range of coefficients almost as high as with Nos. 2 and 3 was obtained. It is apparent, however, that there is a sharper reduction in the low-head coefficients for the smaller than for the larger orifices.

With heads of 0.015 ft. and greater a fair degree of accuracy was possible with the experiments; for heads of less than this it was ex-

tremely difficult to obtain absolute accuracy. By careful repetition of experiments and extension of the curves obtained under the larger heads, it is believed, however, that the results as shown on the curves, even for the lowest heads, are very close to the truth.

The relatively small coefficients of flow under the smaller heads, which appear to be absolutely established by these experiments, necessarily introduced a disturbing element into the measuring device. It was apparent that the accuracy of the measuring device must depend on coefficients of flow for these small orifices being of reasonable constancy. The experiments, however, clearly show that for the smallest orifice the coefficients are reduced from 88% for a head of 0.3 ft. to about 60% for a head of 0.01 ft., a reduction of about 33%, an amount that would render the apparatus useless for scientific purposes.

The difficulties created by the varying coefficients of the small orifices have been overcome in the volumeter by a special feature which increases slightly the operating head, as will be referred to later.

It is an interesting fact that no advantage in flow coefficient was apparent from the curved approaches of Orifices Nos. 1, 2, and 3, in $\frac{3}{16}$-in. plate. The same, or even greater, discharges were found when the plate was reversed and the curved approach was turned down stream; moreover, Orifice No. 4, in thin plate without any curved approach, gave distinctly higher results than Orifice No. 1.

In addition to experiments with water, runs were made using oils. A careful investigation of oils on the market was made to find one having a viscosity which did not change very materially under changes of temperature such as would be encountered in a water-measuring device under working conditions (see Fig. 7 for viscosity tests). The oils most nearly approaching these conditions were kerosene, a petroleum product known commercially as white neutral oil, and another petroleum product known as glymol. The latter is a thick, clear oil, used generally for medicinal or surgical purposes. It has a viscosity ranging from about two to five times that of water or kerosene, within a range of temperatures between 32° and 100° Fahr. A series of careful runs was made with glymol and kerosene, the results being shown on the accompanying diagrams. It will be noted that the coefficients of flow for glymol ranged very low, the highest being less than 30% for a head of 0.6 ft. It is clear that no satisfactory results can be obtained by using the flow of this medium

in a measuring device. Kerosene gave results very similar to those of water, but about 10% less in amount.

A difficulty of appreciable moment in connection with this device is that involved in inducing a current or jet of liquid or gas of less specific gravity than water to discharge into the latter without sacrificing any of the head due to velocity of the stream which is being measured. It is to be borne in mind that the apparatus must necessarily operate under extremely small heads, such, for instance, as 0.01 or 0.02 ft., as due to velocities as low as 1 ft. per sec. or less. Therefore, there is no energy to spare in the velocity head of the stream being measured, all of this head being required for the purpose of recording; in other words, the operation of the apparatus itself must be carried on with power entirely outside of the static or velocity head of the stream.

If a vessel containing water is superimposed on a tight vessel containing air, and if these be connected by an orifice less in diameter than about 0.011 ft., it will be found that the water will not flow down through the orifice after the air in the lower vessel has been compressed to a density sufficient to resist the pressure of the superimposed water. Surface or skin tension of the water itself, no doubt, has much to do with this resistance, but, whatever the reasons are, it will be found that the water pressure is balanced by the air pressure plus this frictional resistance. If the orifice is made larger in diameter than 0.011 ft., there will begin to be a tendency for the air and water to pass each other through the orifice, the air escaping by bubbles and marked disturbance of the water. With smaller orifices, however, there is no passage of air and water, and a condition of equilibrium is maintained.

If oil is substituted for air in the lower vessel similar results will be observed, but to a much more marked degree, depending on the viscosity of the oil. The repulsion between oil and water and the surface tension of each medium creates a balance of forces, even with connecting orifices of very considerable size between the vessels, so that the heavier medium will not sink into and displace the lighter one. This refusal of the different media to pass each other through small orifices is a feature of importance in working out the measuring device herein referred to.

It was found by experiment, moreover, that a very appreciable force was necessary to break the seal of surface tension and induce a flow between differing media through the small orifices required in this apparatus. The amount of this force differs with the size of the orifice and the character of the medium. With an orifice 0.001 ft. in diameter, a head of nearly 3 in. was necessary to overcome this resistance and induce air to pass upward into water. With oils the resistance is less than with air, but in all cases there is an appreciable resistance to be overcome.

From the foregoing it will be understood that a substantial operating head or force must be provided from other sources than the static and velocity heads of the flowing stream. In the volumeter, this force has been obtained from gravity operating between the two vessels, in which the heavier medium is at the top and consequently tends to sink to the bottom and displace the lighter medium there contained. The apparatus provides means whereby the force of gravity is exactly controlled so as to furnish operating power and to apply the necessary correction to the discharge coefficient of the controlling orifice.

Referring again to the reduced coefficient of the flow with these small orifices under low heads, a study of the curves of coefficients seems to indicate clearly that the reduction is largely due to some obscure retarding force, such as surface tension, which actually absorbs a portion of the operating or velocity head applied, and is, to a considerable extent, if not entirely, a constant in itself. Thus, with heads as low as 0.01 ft., the coefficient of flow may be as low as 50%, which would indicate the velocity of the jet to be about 0.4 ft. per sec. If the coefficient had been about 90%, as in the case of the higher heads, the velocity would have been about 0.7 ft. per sec. Thus the loss in velocity due to surface tension or some similar cause is about 0.3 ft. per sec., an amount which would correspond with an approximate loss of head of about 0.007 ft. Thus the addition of a constant correction of some small amount like this had been found practically to eliminate the variant in the discharge coefficient for the small orifices, and to give a resulting accuracy to the device, which is forcibly brought out by the curve of discharge shown in comparison with the curve of theoretic velocities and discharge in Fig. 8. These results are of the highest practical importance.

PORTLAND, ORE. DEC. 31, 1914

FIG. 7.

In the determination of discharge of the volumeter for different heads, as given in Fig. 8, the following method was used: The apparatus was set up on a table, the influent and effluent pipes being connected by $\frac{3}{4}$-in. rubber hose with two vessels open at the top and filled with water. The differences in head between the water levels of these vessels was carefully measured by a hook-gauge, and the quantity of water actually passing into and out of the apparatus was measured

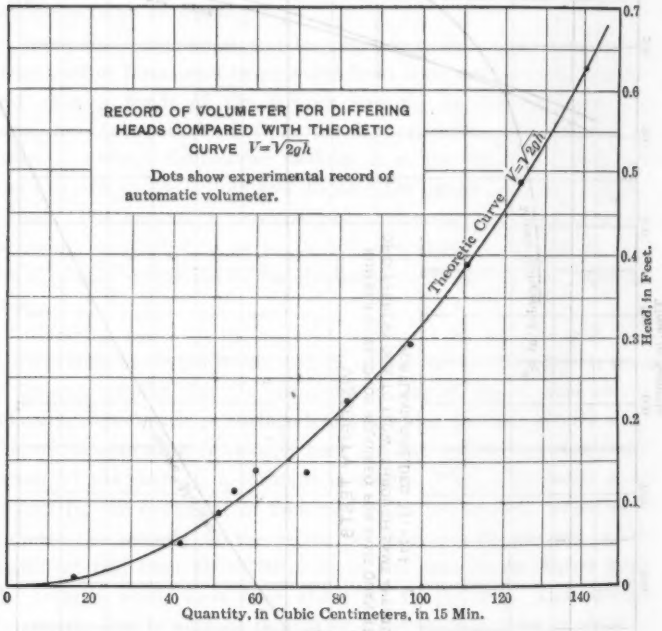

FIG. 8.

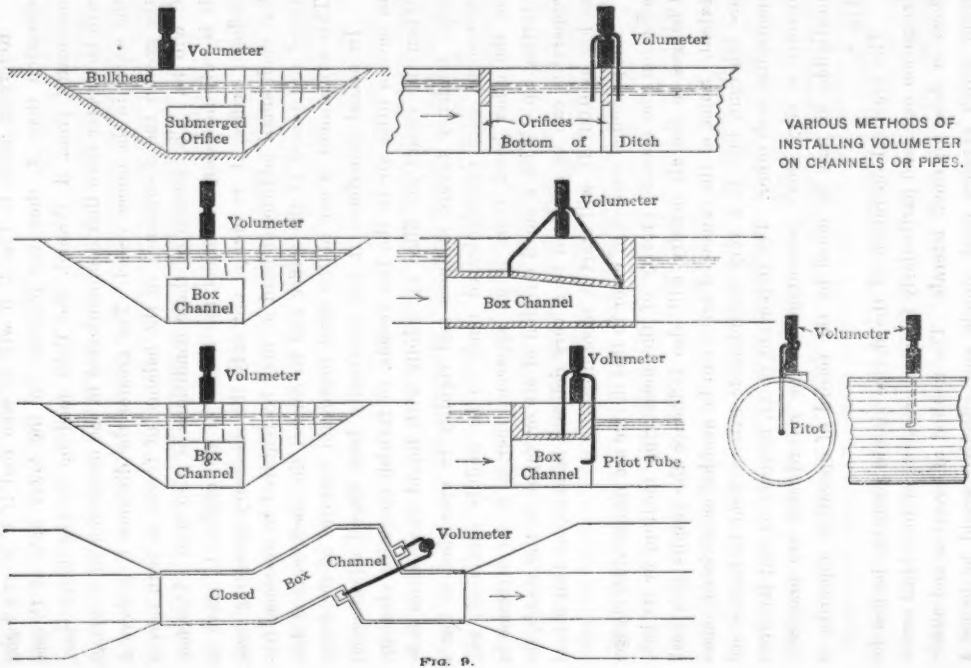
by accurate glass graduates and checked by the scale on the volumeter itself.

Extreme accuracy was possible in all measurements, and the latter were carefully checked and repeated a number of times. On Fig. 8 the quantities passing are expressed in cubic centimeters per 15 min. This is a purely arbitrary measurement, and might as well be expressed in some other form; actually, the quantities measured



VARIOUS METHODS OF INSTALLING VOLUMETER ON CHANNELS OR PIPES.

FIG. 9.

were the result of much longer runs than 15 min., usually being 1 or 2 hours in each case.

Referring again to Fig. 1, it will be seen that if *C* is at a higher elevation than *A*, then the pressure on the lower side of *C*, communicated from *A* through the light medium in the lower vessel, will be greater than that communicated to the upper side of *C* through the water in the upper vessel. The greater the distance *C* is above *A*, the greater the discrepancy in the balance of forces on both sides of *C* will be. The reverse of these conditions is also true. Therefore, it is only necessary to adjust the height of the orifice, *C*, above the influent orifice, *A*, to obtain, not only the necessary operating force, but such small additional head as may be required to overcome frictional resistances at the orifice and to correct the coefficients of flow. This adjustment is one of the most important features of the device.

In actual experience it has apparently been found advantageous to have a little air in the two vessels, to furnish operating elasticity. When the vessels are filled up solidly with liquid there seems to be some tendency toward stiffness and rigidity in operation, so that a movement once communicated tends to be unduly continued; and, on the other hand, there is an apparent inertia to be overcome in starting up. With a small cushion of air or vapor in the vessels, the apparatus can be adjusted to a very delicate balance, so that a head as low as 0.001 ft. will start it recording.

The principal sources of error in this device are temperature changes affecting the specific gravity of the measuring medium or its bulk. Changes in the air density will also influence the results to a small extent. Some of the causes of error can be avoided or obviated; others are inherent, but, to a very considerable extent, tend to balance and neutralize each other. The important point, however, is that the errors involve a very small percentage of the record and are practically negligible, as may be noted by the record of operation appearing on Fig. 8.

The practical operation of the device should probably be first for irrigation uses, and particularly for measurements of individual service flows or flows in small laterals. The method of erection and attachment which appears most simple and effective would be to use a section of box flume or pipe, a few feet in length, at the point of measurement, or two submerged orifices, as shown on Fig. 9. The

device would be connected with the stream by permanent iron pipe connections and protected by a small box cover. Recharging of the apparatus could be accomplished without disturbance other than merely emptying one vessel into the other.

The device records volume at any given time. No record is made of the various changes in rates of flow during the period of observation. If this is desired, however, it is a mere matter of adding clock-work recording mechanism. A continuous roll of sensitized paper passed by the gauge will enable a photographic record of variations in flow to be obtained. Such a record will be a mass-curve of the flow during the period of observation.

The device, as applied to irrigation use, has the advantage that it is independent of such matters as drifting sand, weeds, or any floating or suspended trash. Nothing in suspension will pass into the influent pipe, which has practically no velocity of flow and has, moreover, an upward course. Solid matter if placed in the influent pipe would in fact settle back into the stream. Even if suspended or floating material should get into the measuring vessels, it would not pass through the controlling orifice on account of the internal arrangements. This has been put to very severe test in the experimental run, as the water used in this was full of impurities and suspended matter.

An apparatus like this, of course, must be set with skill by one who understands the principles of its operation. With proper setting, its further operation is so simple and automatic that any ditch rider or mechanic of average intelligence will be able to reset and read it each day or whenever necessary. The device is as near a self-contained and self-operating one as can well be imagined.

The device should be cheap. It ought to be made and sold for a few dollars, which should cover everything, including all the necessary pipe and fittings. This should place it within the reach of all.

For use on water-works systems or for industrial purposes its simplicity and cheapness should render it valuable and enable a more intelligent understanding to be had of many operating conditions that have hitherto not been fully understood owing to the cost of large meters and the skill required in their operation and the deduction of results.

DISCUSSION

Mr. Booth. GEORGE W. BOOTH,* M. AM. SOC. C. E. (by letter).—This very ingenious and simple device should have a wide field of application, provided it proves in service to be as generally applicable to the various conditions of fluid flow as Mr. Hopson's tests lead him to believe. As he observes, one of the obstacles at present met in providing measuring devices of reasonable accuracy is the cost of putting in and maintaining the apparatus.

There appears to be no reason for not using this device in measuring the flow in pipe distributing systems, provided the velocity of flow is sufficient to start the recording apparatus, as it usually will be in such systems; Mr. Hopson states that the velocity head required for this is as low as 0.001 ft.

The writer has been interested to determine whether the volumeter could be used on fire line services to buildings equipped with automatic sprinklers or stand-pipes. If it could be certain of use solely for fire protection, there would be no call for a meter, because this use occurs only at very infrequent intervals, and the total consumption is comparatively small; however, the experience of some water departments in connection with the illicit use of water for other purposes has been such that the placing of some form of meter is being required, and the cost of a satisfactory one is a considerable objection, especially in the smaller buildings.

The most common size of fire line service is 6-in., with a 4-in. pipe for buildings having less than about 6 000 sq. ft. of floor area, and an occasional service of larger size. If the minimum velocity head at which the apparatus will register is 0.001 ft., corresponding to a velocity of about 0.3 ft. per sec., flows of less than about 22 gal. per min. in a 6-in. pipe, and about 10 gal. per min. in a 4-in. pipe, will pass unrecorded. A meter not capable of measuring these smaller flows would hardly be satisfactory for this service, and it would probably be necessary, as is the present practice with other types of meters, to provide for measuring them through a by-pass, with an arrangement to divert the flow to the main channel automatically at such times as a large supply and small loss of head are required.

Mr. Hopson. E. G. HOPSON,† M. AM. SOC. C. E. (by letter).—Mr. Booth suggests the possible usefulness of the automatic volumeter for metering individual fire mains supplying sprinkler systems, and it would seem that this proposition may have considerable merit.

With regard to these fire mains, the conditions, as understood by the writer, are as follows: Such mains are intended for use solely for

* New York City.

† Portland, Ore.

Mr. Hopson.

fire protection, and, ordinarily, are merely filled with water under pressure which is not drawn upon, save possibly for occasional flushing or test. The quantity of water used strictly for fire purposes is negligible, under ordinary conditions, where no fires occur, and, even when they do, it is relatively small as compared with the daily use of water for domestic or mercantile purposes. There is no object in measuring the water used strictly for fire purposes, because its quantity is insignificant at all times, and the idea of economy or limitation in its use is not to be considered.

The illicit use of water from these fire mains has always been a standing annoyance, and has led to the requirement referred to by Mr. Booth that these services be metered. That, again, introduces another difficulty, as a meter for a 4-in. or 6-in. main is not only expensive, but is not suited for the detection and registration of illicit drafts, which, though small in each case, are considerable in the aggregate, owing to their frequency. In practice, this difficulty has been met, in part by the introduction of a small metered by-pass which permits the complete registration of all such uses, but has the disadvantage that the main supply is necessarily cut off, and dependence must be placed on some automatic process of throwing in the main during an emergency. From the fire protection standpoint, a system dependent on any automatic control has decidedly objectionable features.

As Mr. Booth correctly points out, if the volumeter can only operate under a velocity head of 0.001 ft. and upward, considerable quantities of unregistered water might pass through a 4 or 6-in. main, if dependence was placed on the apparatus. This estimate is that as much as 22 gal. per min. on a 6-in. pipe, or 10 gal. per min. on a 4-in. pipe might go undetected.

The exact head necessary to start the volumeter recording is not known, no special test having been made for that purpose. The writer has found, however, that it will start and stop under changes of head as small as 0.001 ft. This is a very small head, and perhaps it will be well to assume for present purposes that it is the limit of accuracy. Such a head corresponds to a velocity of about 3 in. per sec. If the fire main can be made to discharge through a reduced cross-section so that this velocity will correspond to a relatively small discharge, then measurement by the volumeter, taken at the contracted section, may be possible and may be sufficient for the purpose in view.

It is suggested, therefore, that a reducer be inserted in the main, possibly in the manner indicated in Fig. 10. This shows a 4-in. main reduced to a 1½-in. throat in about 1 ft. of distance and then correspondingly expanded to the original diameter. The reduced area of cross-section is about one-seventh of the full section, and the velocity at the throat is seven times that in the main. Assuming a working

Mr. Hopson.

velocity of 6 ft. in the fire main, or a discharge of 230 gal. per min., there would be a loss of head (due to the reducer) of only about 3½ ft. or about 1 lb. pressure. Thus, for all practical purposes of fire protection, the fire main would be unthrottled and wholly free from objectionable automatic control.

The volumeter could be connected with the reducer by the influent pipe, *a*, and the effluent, *b*, similar in manner to the connection of the registering apparatus of a Venturi meter. It might equally well be connected by a Pitot tube at the throat as at *a'* and a piezometric connection at *b'* below the reducer, for the effluent. Such an apparatus, in a 4-in. main, would detect and register uses of water as small as 1.4 gal. per min.; or in a 6-in. main, a little more than double that quantity.

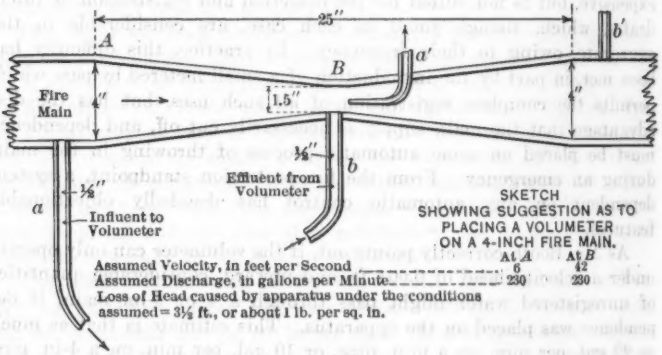


FIG. 10.

Though this minimum might still exclude very small drafts, or even small constant leaks, it would show clearly all the ordinary drafts likely to be made in a mercantile establishment, such as the drawing of a pail of water, the use of a hose, or similar details.

The limitation of the apparatus with reference to minimum measurement is governed by the maximum practical velocity at the throat. This has been assumed at 40 ft., or perhaps a little more, which apparently is possible without any sensible sacrifice of working pressure in the fire main. If, on the other hand, there is an ample sufficiency of pressure in the fire main, so that as much as 20 lb. pressure can be sacrificed at the reducer, it might then be possible to contract the diameter of the throat still more, and thus correspondingly increase velocities and secure a measurement of flow as low as about ¾ gal. per min. on a 4-in. main.

An advantage of such an arrangement is that it is good from the fire-protection standpoint, and the cost should be very small. The

25-in. reducer would be cheap, and the volumeter and connections should cost only a few dollars. The apparatus has no working parts, and will not get out of order by disuse, but it would be necessary to protect it from frost. Mr. Hopson.

One objection to such an arrangement, called to the writer's attention by Mr. Booth, is the fact that the contracted section of the main has already been objected to by underwriters in the case of the Venturi meter, because of the fear that foreign matter, such as a block, or a stone, or other article, unwittingly left in the pipe when it was laid, might become lodged in the throat and entirely block the system. This objection, the writer believes, has met with considerable support, but for reasons that do not appear to be well founded. If there is any real danger to be feared on this score, it can be absolutely removed by the introduction of a coarse screen in the main above the contraction. Such a screen, having a mesh of heavy wire, or rods, say, at 1-in. intervals, would prevent any article large enough to block the throat from reaching it, and would hold it at a point where its blocking effect on the main would be inappreciable and where it could be removed.

Paper No. 1359

THE ASTORIA TUNNEL UNDER THE EAST RIVER FOR GAS DISTRIBUTION IN NEW YORK CITY*

By John Vipond Davies, M. Am. Soc. C. E.

With Discussion by Messrs. F. Lavis, Milton H. Freeman, W. H. Bradley, James F. Sanborn, Edward Wegmann, R. C. Kellogg, W. W. Brush, Thomas H. Wiggin, William Cullen Morris, and John Vipond Davies.

Synopsis.

The object of this paper is to describe in general the design and construction of a tunnel of large magnitude, but generally simple in character, and to treat more particularly certain difficulties due to physical conditions encountered and methods used in overcoming them.

The work described consisted of sinking two shafts, 242 and 277 ft. deep, respectively, and driving a tunnel, 18 ft. on the vertical and 19 ft. on the horizontal axis, between these shafts, a distance of 4 662 ft., through rock under a river with a depth of water of 100 ft. The main problem was to drive through a zone of decomposed rock extending on the line of the tunnel for a distance of 450 ft.

The paper is divided into fifteen parts, as follows:

1.—History of project and economic reasons for removal of gas plants from Borough of Manhattan to remote districts, by providing transmission of gas through a tunnel under the East River.

2.—General description of the construction.

3.—Description of the plant.

* Presented at the meeting of October 6th, 1915.

4.—Sinking of the shafts, 30 and 42 ft. external diameter, respectively.

5.—Tunnel driving through various rocks under normal conditions. Geology of line of tunnel. Details of work accomplished, and rates of progress.

6.—Tunneling through decomposed rocks under heavy water pressure, together with a geological description of the sheared contacts and conditions as actually found. In this part is described the method of thorough exploration of the rock formation by test drilling in advance and the consolidation of decomposed material by cement grouting to produce a rock formation through which the tunnel could be safely advanced by ordinary blasting. It also describes the methods of drilling, both with percussion and diamond drills, in preparation for grouting; the practical application and extent of the grouting operations; the use of buttresses to face rotten rock to permit of grouting; and the use of emergency bulkheads to secure the safety of the work and the employees.

7.—Flooding of entire work by breaking out of seam before it was securely grouted and controlled.

8.—Unwatering the tunnel and finally plugging and securing the source of water inlet and solidifying the rock; the methods considered and those adopted; the use of the air lift; the condition of the Portland cement after grouting; and the final completion of the tunnel excavation.

9.—Cast-steel lining used through the bad rock section. Assumptions as to the design of the lining, the details, and the erection.

10.—Drainage of the tunnel.

11.—Ventilation of the tunnel.

12.—Lighting of the tunnel.

13.—Triangulation and alignment; methods used and results obtained.

14.—Quantities of items making up the work; and details of costs of all work executed under normal conditions.

15.—The laying of the gas mains in the tunnel. Two lines of 72-in. cast-iron pipe, each pipe length weighing 26 000 lb. Heaviest cast-iron pipe ever manufactured. Special machinery designed and used for laying pipe. Special machine designed and made for testing joints of pipes as laid. Jointing and caulking of pipe mains.

The writer has endeavored to give a comprehensive description of the work as a whole, and to emphasize the portion of the paper covering the operation of passing through the zone of bad rock. It is hoped that the photographs and drawings which accompany the paper will assist in making clear the actual conditions encountered in the field.

1.—Historical.

About 35 years ago, before the general introduction of electricity, the production of gas for illuminating and heating purposes within the City of New York had reached such a point, with reference to the occupation of lands for manufacturing plants and local interference with city development, as to have made it desirable to consider the removal of these industries from the densely populated sections of the city.

Consequently, on June 21st, 1886, at the request of Mr. James W. Smith, then President of the Consolidated Gas Company, a report outlining the future policy of the Company was presented by Mr. William H. Bradley, then Engineer of the 44th Street Station of the Company, now Chief Engineer, in which the removal of the gas plants from Manhattan Island was strongly advocated. Following this report, the question was thoroughly ventilated in the public press, with strong advocacy of the suggestion that all companies then manufacturing gas on the Island of Manhattan should remove to sites outside the city, and that a great central manufacturing plant should be created on the Flushing Meadows, from which gas should be piped to a convenient point whence it might be conveyed by tunnel under the East River to Manhattan. For several years, however, nothing was done with this proposition. At that time the Ravenswood Gas Company, having a small manufacturing plant at the foot of Webster Avenue, East River, supplied gas locally in Long Island City. About 1891, this company was reorganized by Mr. Emerson McMillin, its corporate title was changed to East River Gas Company, and it obtained from the Legislature of the State of New York the necessary franchise rights to supply gas to New York City by a tunnel to be constructed under the East River.

In 1892 and 1893 the writer's firm constructed, for this new corporation, a small tunnel (internal diameter 10 ft. 2 in. in the por-

tions which were iron lined and a rectangular section 10 by 8 ft. in the portions in solid rock) under the East River, crossing the two channels and Blackwell's Island. This tunnel (shown on Plate XXIV) extends from the foot of East 71st Street, Manhattan, to the Ravenswood works of the Company at the foot of Webster Avenue, Long Island City. Borings and soundings were made at close intervals across the channels, and as far as information could be obtained (with the extremely rapid current running in the East and West Channels of the East River), there was every reason to believe that the construction of a tunnel on that line would be through a practically continuous bed of rock, although the geological information indicated clearly the intrusion of a seam of dolomitic limestone under each channel.

The work on this tunnel was let out by contract, and proceeded very slowly for a considerable time, when, having sunk both shafts and having turned the tunnel on the Manhattan side of the river, decomposed rock was encountered at the contact between the gneiss and dolomite under the West Channel. The contractors immediately abandoned the work, and it was then carried on by the writer's firm, as Constructing Engineers, for account, and on behalf, of the Gas Company.

This tunnel was at a depth of nearly 100 ft. below mean low water. The depth of the water in the West Channel was 65 ft., but that in the East Channel was only about 30 ft. Under the West Channel two comparatively narrow sheared contacts in the dolomite rock were badly decomposed; under the East Channel the contacts between the Fordham gneiss, the mica schist, and the dolomitic formation were also extensively distorted, and, to some extent, decomposed, but the whole of this tunnel was completed successfully with the use of air pressure, the depth not being too great to prohibit this method of construction.

After the completion of this tunnel the East River Gas Company passed into the ownership of the Consolidated Gas Company, and thereafter, the Astoria Light, Heat and Power Company was organized to construct a great central gas manufacturing plant to supply gas to all the constituent companies. This plant was established on a large tract of property at Lawrence Point, Long Island, at the northerly end of the channel known as Hell Gate.

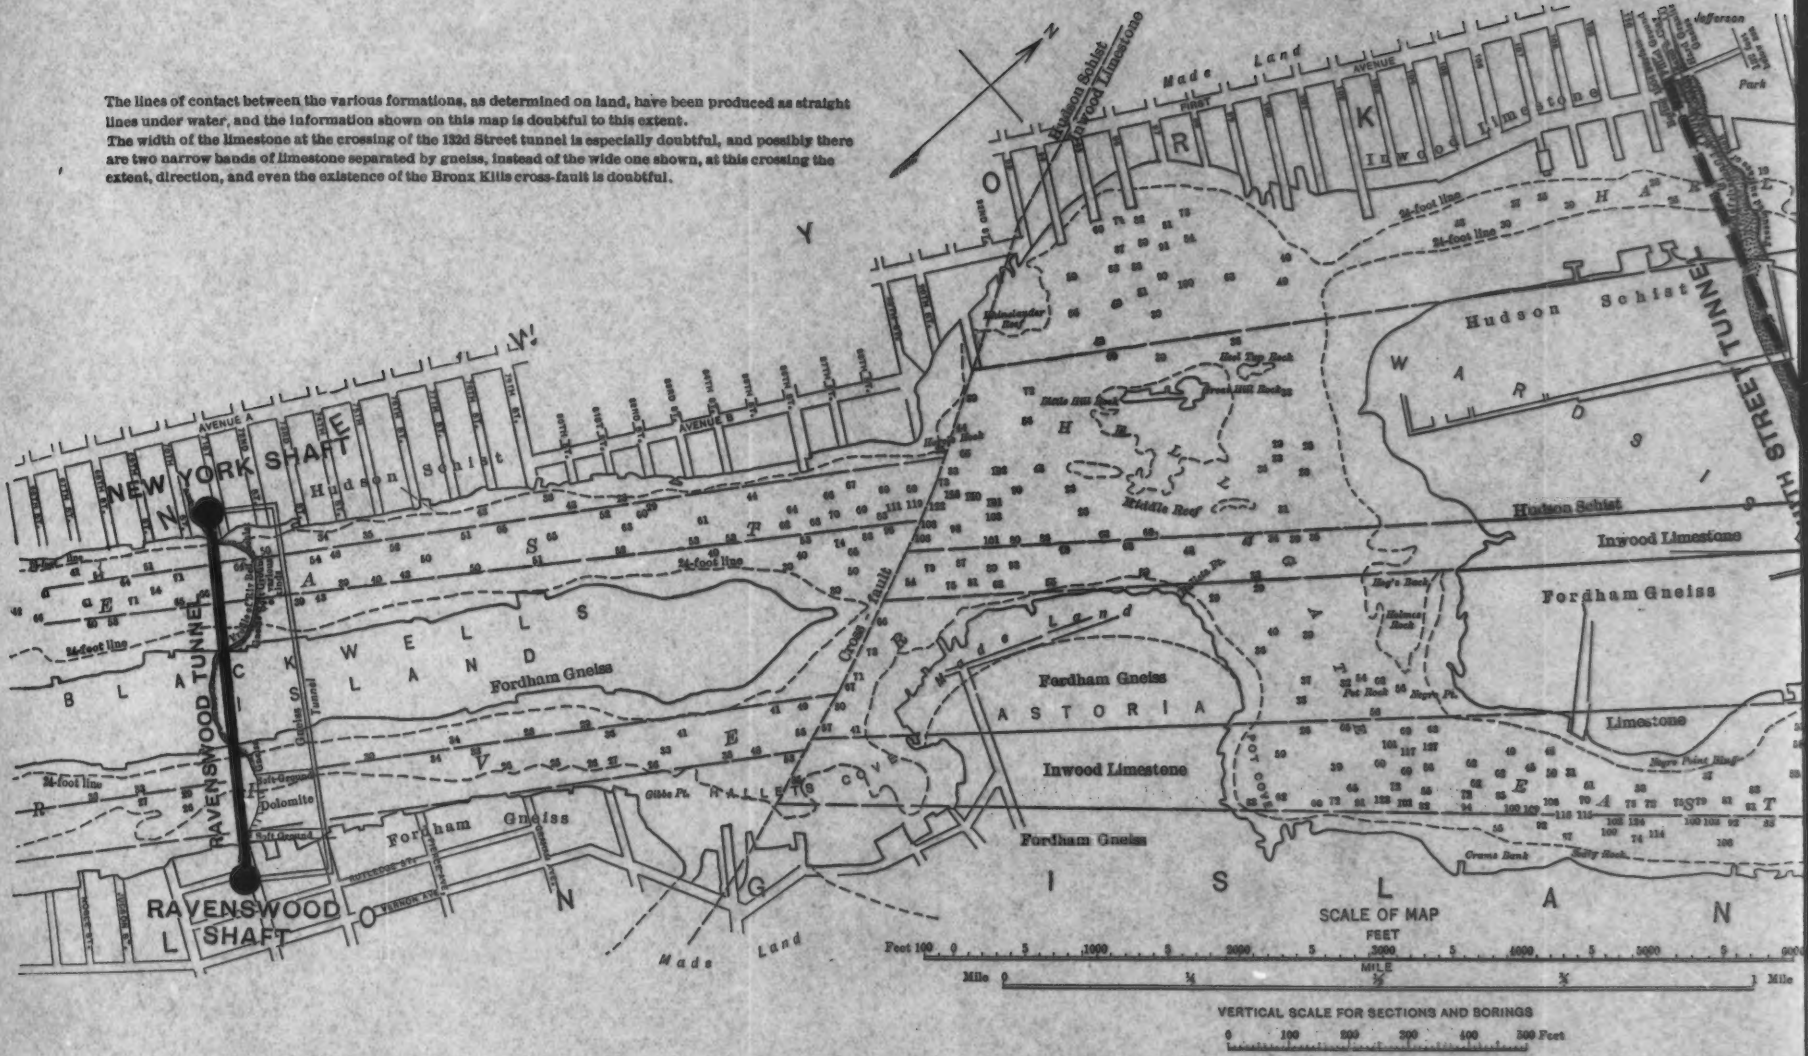
For several years gas from both the Astoria and Ravenswood Plants, for the supply of Manhattan and The Bronx, had been carried through a large pipe line to Ravenswood and thence to Manhattan through the 71st Street tunnel in two 36-in. mains. The supply for The Bronx had been conducted in pipes laid in open coffer-dam construction across the Harlem River, involving a devious detour.

About 1903 it became necessary to consider an independent means of conducting to Manhattan the gas manufactured at the Astoria Plant, as at that time the center of gravity of the gas consumption of the Boroughs of Manhattan and The Bronx combined was at a point south of the Harlem River.

Long legal proceedings, to obtain an easement for a right of way for a tunnel or other means of communication, delayed procedure with this undertaking for several years.

The line of this tunnel was definitely fixed by the necessities of the commercial situation, regardless of geological considerations, as the New York terminus had to be at 111th Street and Pleasant Avenue, where the Gas Company had a distributing station, and the Long Island terminus had to be on the property of the Company at Astoria, just north of Winthrop Avenue. The line, therefore, was laid out between these two points, the Astoria end being kept as close as possible to Winthrop Avenue, in order to conform to the final layout planned for the gas holders of the Company. This line passes under Ward's Island, where it was intended to sink an intermediate shaft for construction purposes, and from this shaft it was contemplated to drive a branch tunnel to a point in The Bronx. Borings were made at the sites of the entrance, outlet and intermediate shafts, and the geological features were studied carefully.

As the depth of the water in the channels on this line was somewhat in excess of 100 ft., and was so great that it was impossible to use air pressure, and as the known geological conditions made it certain that the contacts between the gneiss and dolomite formations would give more or less trouble, it was considered desirable to place the tunnel deep in the rock, in order to minimize trouble from open seams. On the other hand, the necessity (in event of a deeper location) for lengthening vertically the pipes for carrying the gas made it undesirable that these shafts should be deeper than was reasonably



The lines of contact between the various formations, as determined on land, have been produced as straight lines under water, and the information shown on this map is doubtful to this extent.
The width of the limestone at the crossing of the 132d Street tunnel is especially doubtful, and possibly there are two narrow bands of limestone separated by gneiss, instead of the wide one shown, at this crossing the extent, direction, and even the existence of the Bronx Kills cross-fault is doubtful.

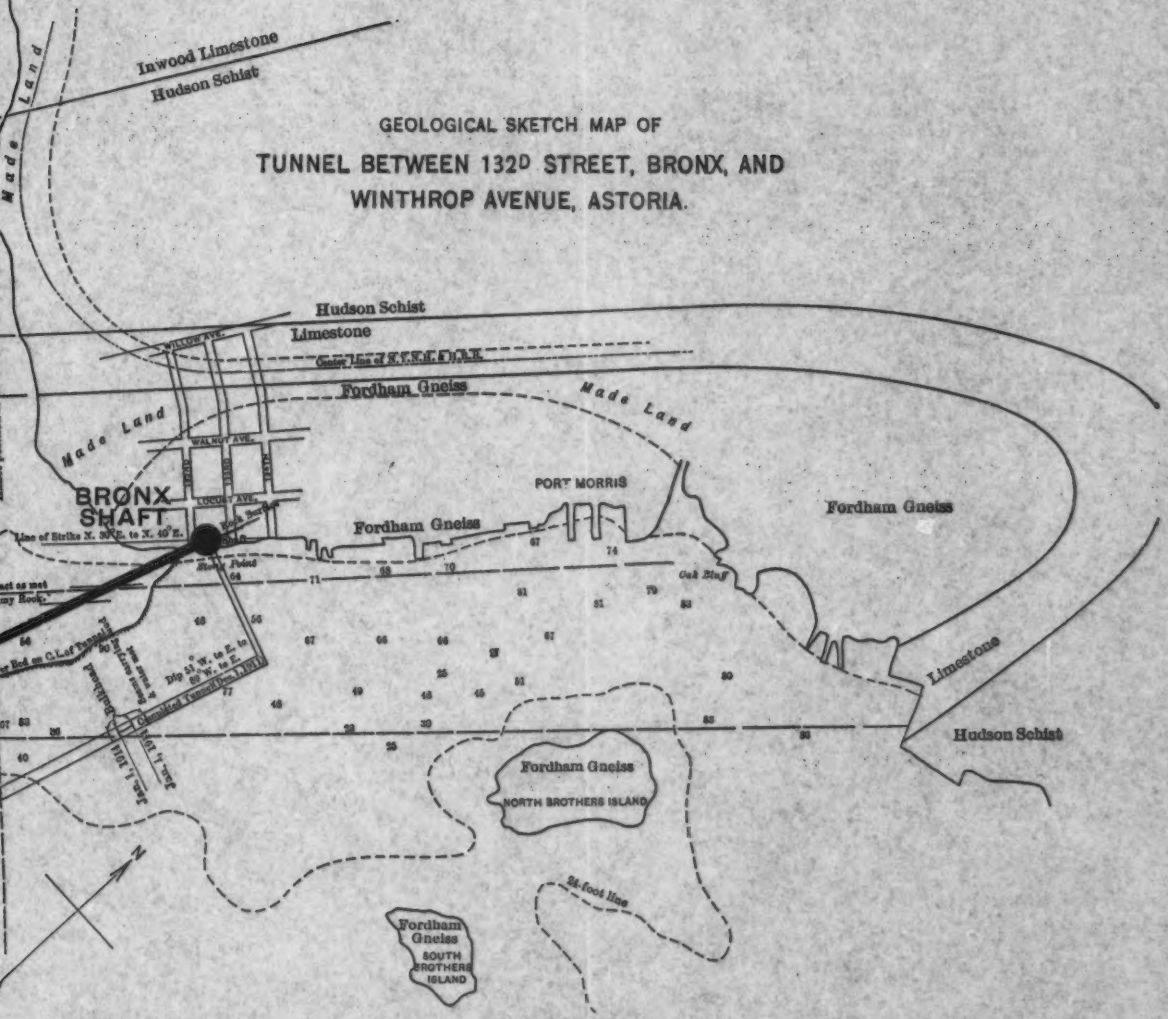
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXX, No. 1359.
DAVIES ON
THE ASTORIA TUNNEL.



necessary to assure that the tunnel would pass below any serious difficulties of geological contact. Ultimately, the depth for the tunnel was decided on as 186½ ft. below mean sea level at the Manhattan Shaft descending to 218 ft. below that level at the Long Island Shaft. Within a prism on this line and grade, easements for right of way were acquired, and all legal proceedings were completed.

As before stated, these legal proceedings consumed considerable time, and in the interim the center of gravity of gas consumption had moved north of the Harlem River, with every indication that it would extend still farther north; and, by the time the Gas Company was ready to proceed with the work, it had become desirable to discontinue, for the time being, the plan for constructing the tunnel on the original line to 111th Street, and, instead, to proceed with that of delivering gas directly from the Astoria Plant to the Borough of The Bronx. At the same time, the Company did not desire, by any means, to abandon its rights to construct at a later date the tunnel from Astoria to East 111th Street, as originally laid out. This rearrangement necessitated the retention of the shaft near Winthrop Avenue, Astoria, and the purchase of land at Port Morris, at the foot of 132d Street, fronting on the East River, on which to construct a shaft as the northerly outlet of the tunnel, near to, and suitable for a connection with, the distribution system of the Central Union Gas Works, at the foot of 138th Street and Locust Avenue, The Bronx.

The location of the underground prism for the easement for construction of the proposed future tunnel to 111th Street determined the depth of the Astoria Shaft for the tunnel to 132d Street, and an allowance for the necessary drainage gradient toward Astoria determined the limitations of depth at the Bronx Shaft. At the same time, the grade of the tunnel was lowered to the utmost limit permissible within the prism forming the subterranean easement, as it was recognized that on this line the axis of the tunnel would be nearly parallel to the line of strike of the rock, and consequently to the planes of contact between the different geological formations to be penetrated, and therefore, in all probability, would involve more difficulties than the previously projected tunnel to 111th Street, which passed almost at right angles across these contacts. However, the

Gas Company considered that, notwithstanding this, it would be simpler and wiser to face the constructive difficulties than to be under the necessity of adopting a new location which would involve a revival of the entire legal proceedings; and, on this basis, the work hereinafter described was designed and carried out. Plate XXV is a profile of the tunnel and the river bottom.

On account of the uncertainties which might arise in construction, as well as for various other reasons, the Company decided not to invite bids from contractors on this undertaking, but to carry out the work departmentally by its own forces, and the writer's firm was retained as Constructing Engineers in respect to the design and construction.

The following description records for the most part a work of tunnel construction of large magnitude, but comparatively simple in character, excepting only that the general location was at a deep level, with access only at vertical terminal shafts nearly a mile apart, and practically entirely below navigable waterways.

The intention, therefore, in the following presentation, is to describe, in outline only, the work of normal character involved in this construction, and to emphasize more particularly the difficulties encountered, and the methods by which they were overcome.

2.—Construction.

The construction involved in this undertaking consisted of a vertical shaft, 277 ft. deep, on the property of the Astoria Light, Heat and Power Company, at Astoria, a vertical shaft, 242 ft. deep, on private property in The Bronx, and a tunnel connecting these shafts.

Anticipating the future construction of the previously planned tunnel direct to 111th Street, Manhattan, the shaft at Astoria was made larger than the one at The Bronx, in order to accommodate the future shaft installation necessary for the two tunnels; and a short portion of the tunnel on the line to 111th Street, Borough of Manhattan, was constructed, so that, as future necessities arose, this tunnel could be extended without disturbing the Astoria-Bronx service.

The necessities for the gas distribution involved the provision of two 72-in. cast-iron mains from Astoria to The Bronx, with space in the upper portion of the tunnel for future developments and utilities.

Decomposed Limestone
Medium Hard Gneiss

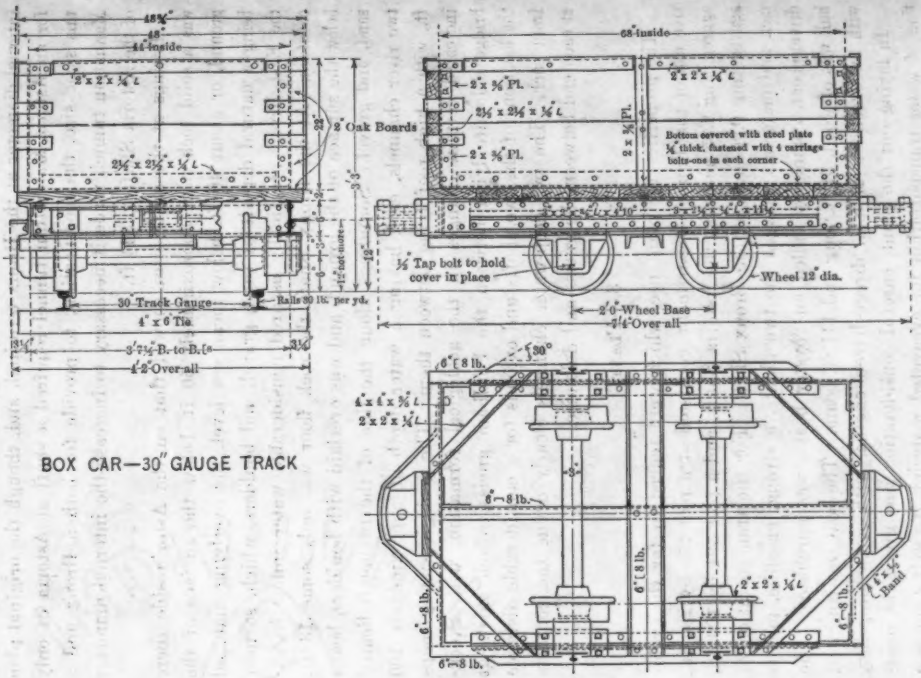
This caused the adoption of a tunnel cross-section 18 ft. on the vertical axis and 19 ft. on the horizontal axis. The vertical pipe risers, elevator frames, etc., made it necessary that the shaft should be 26 ft. in internal diameter at the Bronx terminal, and, though the original plan for an Astoria-Manhattan tunnel required a shaft at Astoria of only this same size, the modification, to provide for both a Bronx and a Manhattan tunnel, made it necessary to increase the internal diameter of the Astoria Shaft to 34½ ft.

Borings at the shaft sites showed that on the Astoria side there was a solid rock floor approximately 50 ft. below the surface of the ground, or about 40 ft. below mean sea level, the overlying material being a natural deposit of sand, gravel, and boulders, which, so near the East River, practically assured considerable water inflow in excavation. At the Bronx Shaft the rock floor was only some 13 ft. below the surface of the ground, and was overlaid with boulders, beach sand, and gravel. Soundings along the line of the tunnel indicated two river channels, each having a water depth of approximately 100 ft., with a high reef lying between them. The geologic survey maps indicated certain changes in the geological formation, with Stockbridge dolomite lying between the Fordham gneiss, which exists at the locations of the two shafts and extends for a considerable distance from each. The two deep-water channels clearly define the contacts at each end between the gneiss and dolomite.

3.—Plant.

The properties for plant use, which were fenced in for the exclusive use of the Tunnel Department, consisted of a plot 255 by 230 ft., aggregating 1.35 acres, at the Astoria Shaft, and a plot 394 by 100 ft., aggregating 0.96 acre, at the Bronx Shaft. For the transportation of men and materials between the two plants, a strong, gasoline, motor-driven boat, commonly called an "oyster boat", was purchased. The hull was of wood, 51 ft. long and 14½ ft. beam. The boat was equipped with an excellent, 25-h.p., direct-driven engine, with screw propeller.

In laying out the plant, careful consideration was given the question of water transportation for excavated material, involving the use of scows and the utilization of the excavated material to fill other lands owned by the Company. A dock existed at the Astoria plant, but there was only a broken rock shore with extremely steep slopes



BOX CAR—30" GAUGE TRACK

FIG. 1.

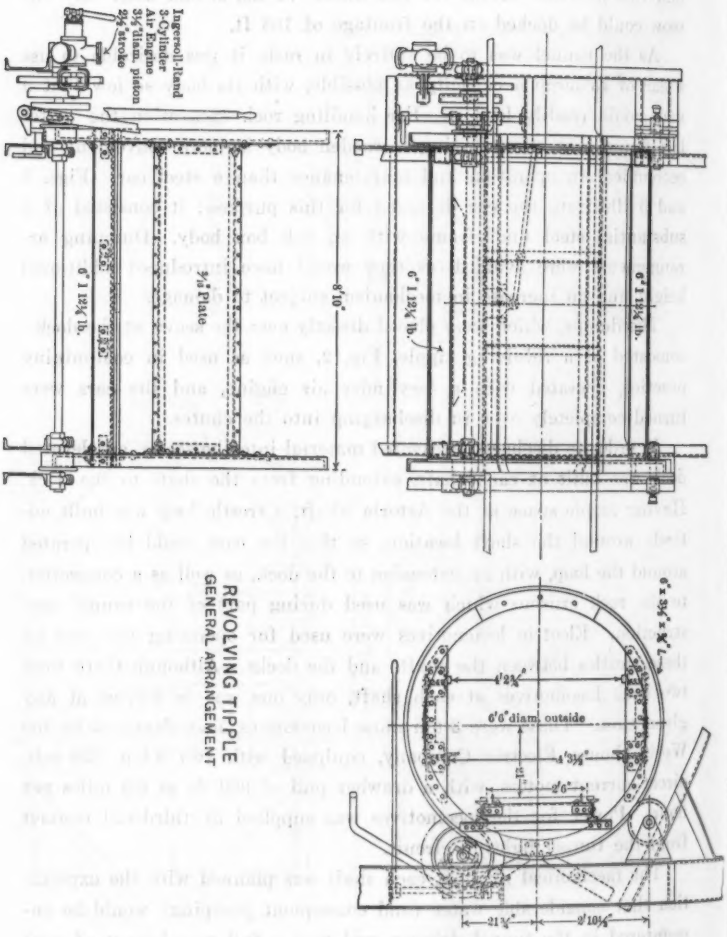
at the Bronx plant, at which site a crib dock had to be built. At the Astoria dock, 230 ft. frontage was allotted to the Tunnel Department, and this provided berths for two scows; at the Bronx dock only one scow could be docked on the frontage of 108 ft.

As the tunnel was to be entirely in rock, it was desirable to use a car of as large a capacity as possible, with its body so low that a man could readily load it. For handling rock excavation the writer has found that a car having a wooden body is more convenient and economical in operation and maintenance than a steel car. Figs. 1 and 3 illustrate the car designed for this purpose; it consisted of a substantial steel underframe with an oak box body. Dumping arrangements were avoided, as they would have introduced additional height and an increase in mechanism subject to damage.

The dumps, which were placed directly over the scows at the docks, consisted of a revolving tipple, Fig. 2, such as used in coal-mining practice, operated with a 3-cylinder air engine, and the cars were turned completely over in discharging into the chutes.

In order to discharge excavated material into the scows, an elevated deck was built at each shaft, extending from the shaft to the dock. Having ample space at the Astoria Shaft, a trestle loop was built entirely around the shaft location, so that the cars could be operated around the loop, with an extension to the dock, as well as a connection to the rock crusher which was used during part of the tunnel construction. Electric locomotives were used for operating the cars on these trestles between the shafts and the docks. Although there were two such locomotives at each shaft, only one was in service at any given time. These were 3-ton mine locomotives, manufactured by the Westinghouse Electric Company, equipped with two 8-h.p. 250-volt, direct-current motors, with a drawbar pull of 900 lb. at 6.6 miles per hour. Power for the locomotives was supplied by third-rail contact from the tunnel lighting circuit.

The mechanical plant at each shaft was planned with the expectation that considerable water (and consequent pumping) would be encountered in the tunnel driving, and that a full complement of rock drills and labor-saving devices would be necessary, and with the intention of constructing half the length of the tunnel from each shaft. The following plant was used.



REVOLVING TIPPLE
GENERAL ARRANGEMENT

FIG. 2.

ASTORIA PLANT.

Boiler-Room.—

Four 302-h.p. Heine water-tube boilers, } 1 840 total boiler h.p.
Two 316-h.p. " " " " }

Six 20-in. Typhoon turbine blowers—L. J. Wing Manufacturing Company.

Engine-Room.—

Two 100-lb. pressure, Ingersoll-Rand air compressors; total capacity, 3 200 cu. ft. per min.

Two 42-in. Ingersoll-Rand after-coolers.

Two 54 by 120-in. Ingersoll-Rand air receivers.

One hot-well tank, 48 in. diameter, 96 in. high—G. Stuebner.

Two 50-kw., 200-ampere, 250-volt, General Electric generators.

Two 75-h.p. Harrisburg Foundry and Machine Company, horizontal engines.

One Walker Electric Company switch-board for 250-kw. generators.

Two 1 200-boiler h.p. Worthington boiler feed pumps.

One 250-gal. per min. Worthington duplex pump.

One surface condenser and feed-water heater combined—12 600 lb. of steam per hour—Wheeler Condenser and Engineering Company.

One vacuum oil separator and simplex pump—12 000 lb. steam per hour—Warren Webster Company and Warren Steam Pump Company.

Two closed water-tube feed-water heaters—800 h.p. to raise 24 000 lb. of water per hour from 60 to 200° Fahr.—F. L. Patterson and Company.

One 30-gal. oil filter—Hall Manufacturing Company.

Surface.—

One 45-ft. derrick.

Two 50-ft. derricks.

Three Lidgerwood Manufacturing Company hoisting engines for derricks.

One 1-cu. yd. Smith concrete mixer and engine.

One No. 4 gyratory stone crusher—Allis-Chalmers Company.

One 8 by 12-in. Buckeye vertical engine.

One 42-in. Ingersoll-Rand air reheater.

Two 3-ton electric mine locomotives—Westinghouse Electric and Baldwin Company.

Blacksmith-Shop.—

One Ingersoll-Rand Ajax drill sharpener.

One Ingersoll-Rand furnace.

Two 36 by 36-in. air forges—Buffalo Forge Company.

Two hand forges—Buffalo Forge Company.

Machine-Shop.—

One 18-in. horizontal lathe—Niles Bement Pond Company.

One 16-in. shaper " " " "

One 24-in. drill press " " " "

One ¾ to 1½-in. bolt-threading machine—Wells Brothers.

One 2½ to 8-in. pipe-threading machine—Curtis and Curtis.

One power hack-saw—Frevert Machine Company.

One 12-in. emery wheel—Niles Bement Pond Company.

One 6 by 6-in. vertical engine—B. F. Sturtevant.

Carpenter-Shop.—

One 16 to 20-in. wood-frame rip-saw, 7½ to 15 h.p.—American Woodworking Machine Company.

One swing-saw.

One band-saw, 1-in. saw, 33-in. band wheels—H. B. Smith and Company.

Two Fairbanks grindstones.

One 6 by 6-in. vertical engine—B. F. Sturtevant.

Shaft Hoisting Equipment.—

One 10 by 12-in. reversible, compound-geared, elevator engine—Lidgerwood Manufacturing Company.

One 12¼ by 15-in. reversible, link-motion, single-geared, elevator engine—Lidgerwood Manufacturing Company.

One 66 by 72-in. passenger elevator cage.

Two 66 by 96-in. material elevator cages.

Four 1½-yd. shaft buckets—G. Stuebner.

Three ¾-yd. tip buckets—G. Stuebner.

BRONX PLANT.

Boiler-Room.—

Three 375-h.p., Babcock and Wilcox boilers—1 125 total boiler h.p.

One induced-draft fan and engine.

Engine-Room.—

Two 100-lb. pressure, Ingersoll-Rand air compressors; total capacity, 3 200 cu. ft. per min.

Two 42-in. Ingersoll-Rand after-coolers.

Two 54 by 120-in. Ingersoll-Rand air receivers.

One hot-well tank, 48-in. diameter, 96 in. high—G. Stuebner.

Two 50-kw., 200-ampere, 250-volt, General Electric generators.

Two 75-h.p. Harrisburg Foundry and Machine Company, horizontal engines.

One Walker Electric Company switch-board for 250-kw. generators.

Two 1 200-boiler h.p. Worthington boiler feed pumps.

One 250-gal. per min. Worthington duplex pump.

One surface condenser and feed-water heater combined—12 600 lb. of steam per hour—Wheeler Condenser and Engineering Company.

One vacuum oil separator and simplex pump—12 000 lb. steam per hour—Warren Webster Company and Warren Steam Pump Company.

One 30-gal. oil filter.

Surface.—

Two 50-ft. derricks.

Two 8¼ by 10-in. non-reversible engines for derrick—Lidgerwood Manufacturing Company.

One 1-cu. yd. Smith concrete mixer and engine.

One 42-in. Ingersoll-Rand air reheater.

One 60-h.p. vertical boiler—Wickes Brothers.

Two 3-ton electric mine locomotives—Westinghouse and Baldwin Companies.

Shaft Hoisting Equipment.—

One 10 by 12-in., reversible, compound-geared, elevator engine—Lidgerwood Manufacturing Company.

One 12¼ by 15-in., reversible, link-motion, single-geared elevator engine—Lidgerwood Manufacturing Company.

One 66 by 72-in. passenger elevator cage.

Two 66 by 96-in. material elevator cages.

Four 1½-yd. shaft buckets—G. Stuebner.

Three ¾-yd. tip buckets—G. Stuebner.

Tunnel Equipment.

Rock-Drilling Equipment.—

Six Ingersoll-Rand rock drills, 2¼-in. pistons.
Thirty Ingersoll-Rand rock drills, 3¼-in. pistons.
Six Ingersoll-Rand rock drills, 3⅜-in. pistons.
Twenty-three Ingersoll-Rand hand hammer drills.
Sixteen Ingersoll-Rand 5½ by 96-in. drill columns.
Twenty-eight Ingersoll-Rand drill tripods.

Concrete Equipment.—

Two Blaw steel arch and side-wall forms.
Two " " side-wall forms.
Twelve bottom-dump buckets—G. Stuebner.

Grouting Equipment.—

Two 200-lb. pressure, Ingersoll-Rand, straight-line, air compressors.
One 500-lb. pressure, Ingersoll-Rand, straight-line, air compressors.
Two 36 by 96-in. air receivers—Logan Iron Works.

} Total capacity 900 cu. ft. per min. In Engine-room.

Two 500-lb. pressure, cast-steel, grout pans, without engines.
Eight 200-lb. pressure, grout machines and engines—Cockburn Barrow and Machine Company.

Pumping Plant.—

Two	Cameron	piston	pumps,	115	gal.	per	min.
One	"	sinking	"	200	"	"	"
Five	"	piston	"	330	"	"	"
Nineteen	"	"	"	600	"	"	"
One	"	"	"	800	"	"	"
One	"	"	"	1 000	"	"	"

Rolling Stock and Haulage.—

Two 8 by 10-in. endless-cable, haulage engines—Lidgerwood Manufacturing Company.
Four 5 by 6-in. single-drum, hoisting engines—Lidgerwood Manufacturing Company.
One hundred 1½-yd. wooden mine cars.
Thirty "V" steel, side-dump cars.

Ventilating Plant.—

Two 12-in. Sirocco fans with motors—American Blower Company.

One 30-in. ventilating fan and engine—B. F. Sturtevant.

One 42-in. centrifugal blower and engine—B. F. Sturtevant.

4.—Shaft Sinking.

Shaft Sinking in Earth.

Astoria Shaft.—The sinking of the Astoria Shaft began on September 12th, 1910. Steel sheet-piling of United States Steel Company section was used for the exterior sheeting through the earth section, for a depth of 52 ft., and was braced with 16-sided timber frames, 4 ft. apart, strapped at the joints with steel plates, to which were attached turnbuckle tie-rods extending across the shaft for use in maintaining the circular form. (Fig. 4.) The dump trestle having been constructed to circular form at a height of 15 ft. above the ground, and the excavation being removed to 8 ft. below the ground, a frame was prepared to the correct circular form, plumbed accurately below the trestle form, and served as a guide for driving the sheet-piling. The piling was cut in two lengths for the total depth, with joints staggered, and was driven with an Arnott 2 000-lb. steam pile-hammer suspended from a derrick.

Excavation was removed as the sheet-piling was driven, in order to avoid any distortion by over-driving against boulders or rock.

Having sunk the shaft to rock level, excavation was carried down into the rock about 4 ft. below the point of the piling, and concrete was placed to half the ultimate thickness for the full depth of the excavation, in order to secure the sheet-piling and timber frames from injury during the further extension of the shaft construction.

Bronx Shaft.—At the Bronx Shaft, the shallow depth of the overlying soil and material, as well as its character, made it unnecessary to use steel sheet-piling. Wooden sheeting of 4-in. tongued and grooved stuff, supported by 12-sided timber frames, 4 ft. apart, was used through the 13 ft. of earth to rock level; the permanent lining inside this sheeting was concreted on reaching the rock floor.

Shaft Sinking in Rock.

Shaft sinking in rock was carried out by the ordinary methods, the usual practice being to line up with concrete every 30 ft., as the

rock was of treacherous character, and the introduction of the lining insured the employees against accidents.

For hoisting and removing the rock excavated from the shafts, and to avoid the danger of using a swinging bucket operated from the boom of a derrick, the permanent head-frame, Fig. 5, to be equipped later for the use of elevator cages, was erected, with overhead hoisting sheaves and the regular elevator hoisting engines. One of these elevator wells was then fitted with guide-framing below the landing, and at the level of the landing a broad-gauge track crossed the elevator opening, with trap-doors fitted to insure safety. The spoil buckets were hoisted through this trap and landed on a flatcar run through the elevator opening before the hoisting rope was detached.

Water entered from numerous rock joints at various points in sinking the shafts, but not in such volume as to retard the progress of the work, except by the time lost in the removal by the derrick of the pumps and hose when blasting. This shaft water was readily handled in each shaft by one 350-gal. per min. steam-driven pump.

Two water rings were placed in each shaft as the sinking proceeded, in order to intercept the water seepage and prevent it from pouring on the men working below. Each ring was simply a 6-in. wooden shelf with gutter board sheathed with zinc, and a 3-in. pipe extending to the shaft bottom for drainage. Later, these leaks were stopped by grouting, while the driving of the tunnel was in progress.

Astoria Shaft.—At the bottom of the Astoria Shaft the design provided for an enlargement, about 41 ft. high, 34½ ft. wide, and extending some 19 ft. beyond the neat shaft lines. This was to be used ultimately as an operating chamber for the distribution of gas, but it, as well as the short length of 100 ft. of tunnel in the direction of the future Manhattan Shaft at 111th Street, was utilized, during the construction of the tunnel, as a pump chamber and store-room. This enlargement extended 16 ft. below the tunnel invert, and, in addition, contained a 5-ft. circular sump 8 ft. deep, so that ample provision was afforded for the accumulation of the expected water flows and for settling any solid matter carried with the water.

Bronx Shaft Sump.—As the tunnel drained southward toward Astoria, a similar sump was not required in the Bronx Shaft, but ample precautions were taken by the construction of a rectangular sump, 21 ft. long, 12 ft. wide, and 8½ ft. deep.

FIG. 3.—BOX CAR FOR EXCAVATION FROM ASTORIA TUNNEL.

5.—Tunnel Driving Under Normal Conditions.

Bronx Heading.—The Bronx Shaft reached a sufficient depth for turning the heading on February 12th, 1911, and the latter was driven for a short length before completing the shaft and sump, so that tunnel driving really began on March 8th, 1911, and continued under normal conditions through sound, close-grained gneiss until August 29th, 1911. At that time the first appreciable delay occurred when the heading entered the expected contact seam of decomposed, water-bearing dolomite, 771 ft. from the shaft center, at which point the water depth in the river is 80 ft. below mean sea level, and the deep river channel corresponds in location to this dolomitic intrusion.

Astoria Heading.—At the Astoria end, work on the main tunnel did not begin until April 8th, 1911, when the headings of both the Bronx and Manhattan Tunnels were already turned. As in The Bronx, the headings were turned when the shaft reached the level of the floor of the top heading, and prior to completing the shaft sinking; the advance toward The Bronx continued until April 23d, 1911, during which time about 80 ft. of the Manhattan Branch Tunnel were driven. Owing to the large chamber arrangements necessary at the bottom of the Astoria Shaft, work on the main tunnel was not resumed from this end until June 23d, 1911, and it continued without incident until November 7th, 1912, a distance of 3 536 ft. from the shaft center.

Geology.—For the first 1 200 ft. from Astoria the tunnel was driven through a hard, compact, and tough granitic gneiss, requiring heavy drilling and large consumption of powder. For the next 2 336 ft. the tunnel passed through the dolomite, and the passage through the easterly contact between the gneiss and the dolomite was made without any apparent disturbance or shear of the geological structure, a condition quite different from the contact encountered in the Bronx heading, where the geological change was featured by violent shear, accompanied by innumerable water fissures and excessive disintegration. At a point 3 536 ft. from the Astoria Shaft, this heading met the first indications of the water-bearing disintegration of the westerly contact between the gneiss and the dolomite. (Fig. 6.) The final results developed the fact that the entire width of this decomposed contact normal to the strike was some 150 ft., whereas the angle of crossing made

by the tunnel involved a total distance of 350 ft., measured on the axis of the tunnel, or 450 ft. between points of contact on the two side lines.

Excavation.—For the tunnel excavation, the top-heading-and-bench method was adopted, maintaining the bench some 50 ft. behind the heading. During the early part of the work the arch lining was not placed as the excavation advanced, these exposed sections being concreted later by using steel forms, and work was performed simultaneously with, and without hindrance to, the driving of the heading and bench. On deciding to place the arch lining along with the tunnel advance, a system of alternate excavating and concreting was adopted, with excellent results as to progress attained. This method consisted of excavating both the heading and bench from 8 A. M. Monday to 8 P. M. the following Friday, the remainder of the 6-day week (until 8 A. M. Sunday) being occupied in placing the concrete arch. By this method the maximum monthly progress was made, being 269 ft. of full tunnel section excavated and arch lined. The average progress maintained by this method was 53 ft. of heading, bench, and concrete arch per 6-day week, which, in volumetric measure, equalled 675 cu. yd. of neat-line excavation and 81 cu. yd. of neat-line concrete arch.

The average unit drilling and blasting quantities incidental to driving the tunnel 4 274 lin. ft., or 92% of the total length, under normal conditions, are presented in Table 4.

Number of exploders	0.79	0.38	0.57	0.71	0.26	0.46

Overbreakage.—Notwithstanding numerous experiments in the placing of drill holes for face of heading and bench, it was found that neither the gneiss nor the dolomite rock could be blasted without great

irregularity in cross-section. The large quantities of blasting gelatine needed to pull the rock caused considerable overbreakage. Careful and repeated cross-section measurements, checked by the volume of concrete used to complete the lining, indicated that, notwithstanding the particular care taken, overbreakage outside of the neat line of minimum lining section in the sound sections of good rock amounted to 18% in the gneiss and 12½% in the dolomite.

Drilling and Firing.—The typical arrangement and length of drill holes for blasting, for both heading and bench, are given in the diagram, Fig. 7, as applicable to both the gneiss and dolomite, under normal conditions. In all cases holes were started with 3-in. drills, which were reduced ¼-in. in diameter with each 2-ft. advance, to a final diameter of 1¾-in. for the 12-ft. holes.

Fig. 7 also indicates graphically the arrangement of wiring, and the order of shooting, the holes.

Two double-strength "Victor" fuses were always used in regular course to insure the proper explosion of charges.

All firing was done by magneto batteries maintained about 500 ft. back of the heading, the wire connections to the heading always being strung on the side of the tunnel opposite that on which electric light wires were placed.

Both for heading and bench excavation ⅜-in. steel shoveling plates were used on the floors for facilitating the mucking operations.

In the varied classes of rock throughout the tunnel headings the speed of drilling was 9.9 lin. ft. per hour per percussion machine. The bench drilling was easily maintained at the equivalent rate of progress.

Practically all the best known brands of drill steel furnished in the New York market were tried out on the work, resulting in the adoption of "ABC non-tempering" steel, which, in these rocks and under the conditions, was found more durable and showed less breakage in dressing and drilling than the others.

The average progress of excavation attained during the tunnel driving under normal conditions, consisting of 4 274 lin. ft., or 92% of the ultimate length, and, based on the advance of one heading only, is given in Table 5. In this tabulation only the total accumulative time chargeable to excavation is considered, with a 24-hour actual working day as the unit.

Based on the results in Table 5, the average monthly (30-day) advance of completed tunnel, excavation only, was 284 lin. ft., or 4 054 actual cu. yd., in one heading.

Although the rate of progress was not as great as in other tunnels, of which reports have been published, the results obtained are thought to be very satisfactory, considering the general conditions of hoisting from a deep level, particularly as at no time was it considered by the management desirable to enter into the system of bonusing men to obtain record results. The entire work was carried out on a normal wage basis, without any attempt to offer other or special inducements to the labor to accomplish records. The progress of the work was perfectly regular and remarkably uniform, both at the Bronx and Astoria Shafts, up to the time of meeting the contact of decomposed rock at each end.

Concrete Arch.—The portion of sound rock tunnel driven from both the Bronx and Astoria Shafts was a hard, solid structure, but the rock indicated extensive jointing, with a tendency to scale away and for blocks of rock to fall without warning, a condition due to the character of the rock and also to the heavy blasting operations. Therefore what had been anticipated to be an untimbered tunnel, necessitated early the consideration either of timbering or of carrying the lining along with the tunnel operations, in order to insure the safety of the workmen. After careful consideration of the advantages and disadvantages of these two methods, it was decided to construct the arch lining, and, on account of the original cross-section adopted, to

finish this arch lining to a skewback intended for the bottom concrete in which the permanent cast-iron gas mains were to be solidly embedded; this arch lining, hanging to the arch, was supported only on the irregularly jointed section of the rock walls.

Change of Design.—From the commencement of this work it had been contemplated to embed the cast-iron gas pipes solidly and permanently in concrete, and to make a floor above them, but, after 2 867 ft. had been lined in this way, the design was reconsidered and a revision made, whereby the pipes would be left exposed and a deck would be inserted above them. The tunnel has been left completed according to this plan (Fig. 8). This obviously necessitated, subsequent to the completion of other parts of the tunnel lining, cutting out portions of the arch lining and skewback which had previously been constructed. In the remaining length of the tunnel, the arch concrete was supported by timber sills on posts, the side-walls and invert not being placed until the complete excavation of the tunnel from end to end, when the sills and posts were removed as the wall lining proceeded.

This method of procedure was peculiar, in that, for the entire job, the arch lining was first executed. Then, when the tunnel was holed through, and the steel lining, hereinafter described, was being erected in the decomposed section, the invert was put in place by trimming the rock floor, in lengths ahead of concreting and laying the invert, to accurately placed side-forms. The forward end of each length of invert was laid out with a curved cross-form which gave accurately the section of the concrete to be laid; this was swept with straight-edges, using the last completed length of invert for the rear sweep and a wooden form for the forward end. The joints at the side-forms, as well as the cross-joints, were designed so as to lock thoroughly with the abutting concrete to be placed later. On the completed invert, after it had come to strength, was laid a track of 60-in. gauge, on which were operated two complete collapsible steel forms, each 50 ft. long; and these were used for the construction of the intervening side-walls, the two side-walls being concreted simultaneously. These forms, Fig. 9, were set up 100 ft. apart, and were advanced 100 ft. at each move, so that each form was used for alternate lengths of side-wall lining, thus permitting the setting up of one form while the concreting was proceeding in the other; this enabled continuous working operations.

Although these forms ran on the 60-in. track laid on the tunnel invert, they had on the bottom frame a standard tunnel-gauge track, with a short incline at each end, so that other operations in the tunnel could proceed by running the tunnel cars through the lower portion of the steel frame. There was an elevator at each end of each form to raise the concrete cars to the upper level, so that they could be run to any point for dumping. The collapsible feature of the steel forms was obtained by using jacks and turnbuckles, and the upper platform of the forms, which was the dumping platform, was practically at the springing line of the arch where the joint was made between the side-walls and the arch already in place.

Before placing the forms the surfaces were well oiled. The moving was done by a small air-driven engine on the dumping platform. This engine was also used to operate the elevator. These forms worked admirably after they had been reconstructed, to some extent, to meet the conditions. The progress obtained with their use was one 50-ft. section each working day, and this rate was maintained with almost perfect regularity for a length of 3 310 ft. of tunnel.

The proper keying of the side-wall concrete to the arch skewback was accomplished, after a number of experimental methods were tested, by forming a wooden chute at the base of the joint and to a level of about 1 ft. above it, through which wet concrete was filled in and rammed into the joint with rods, in order to work the concrete into close contact with the arch skewback and enable the air bubbles to escape. This left a projecting lump of concrete at the joint, but, just prior to moving the forms forward, these chutes were removed and the projecting concrete was chipped off to the neat lines while the concrete was still green. The results of this method were quite satisfactory.

Throughout the work of placing the concrete lining in the arch, side-walls, and inverts, it was considered, owing to the heavy pressures which would come on the lining by any seepage of water, that all voids between the arch section and the solid rock should be entirely filled with concrete. Plums of broken stone, however, were used freely where the concrete exceeded in thickness the neat section. Consequently, no loose packing of rock behind the arch or walls was done in any portion of the work, and, throughout the tunnel, on the com-

pletion of the entire lining from end to end, grouting was carried out by the use of grout pipes which had previously been left projecting from the lining so as to insure absolute solidity of the lining.

6.—Tunneling Under Adverse Conditions Through Decomposed Water-Bearing Dolomite.

As stated previously, no evidence of any shear or disintegration was disclosed at the eastern contact between the gneiss and the dolomite; but the western contact, as encountered from the Astoria end, was featured by some 354 ft. (along the tunnel center line) of highly decomposed dolomite with a heavy flow of water. It is interesting to note that, of this 354-ft. belt, the eastern side was advanced to a farther state of decomposition than the western, the rock mass containing countless seams of decomposed material and pockets of residual clay, all so disintegrated and distorted that the cleavage planes were not distinguishable, and though the strike maintained regularity, the dip was most irregular; in fact, at numerous points it was indeterminable.

The seams were so extremely decomposed that the material consisted only of a micaceous greensand, so porous that, on exposure, water quickly formed a free passage. Usually, these seams were little better than loose sand, although at times they choked the rock seam to such an extent as to yield practically no flow of water.

The first contact with the decomposed rock (which was met in driving the Bronx heading) seemed to indicate the likelihood of getting through the contact without serious difficulties, as the tunnel, after careful grouting, was advanced a considerable distance in rock, which, though excessively distorted and water-bearing, had sufficient strength to carry the pressures without danger. At the same time, it was desirable to protect this heading as it advanced, and the arch was carried on heavy timbering in order to guard against falling rock. Having extended this length on timbering, it was thought that the insertion of cast-iron lining for this section might enable the work to advance successfully, particularly as the rock appeared to be getting stronger and harder beyond the first point of contact. As immediate delivery could be obtained of cast-iron segments made from the patterns from which the Pennsylvania North River Tunnel segments were constructed, a short length of 50 lin. ft. was cast, delivered, and promptly

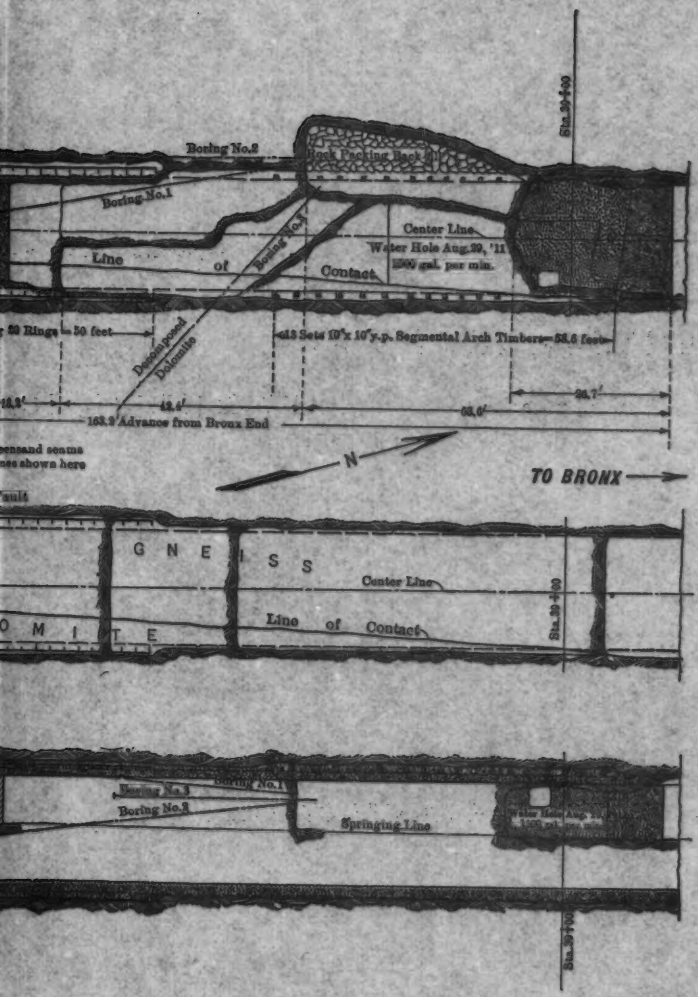
VOL. LXXX, No. 1359.
DAVIES ON
THE ASTORIA TUNNEL.



erected in this wet, water-bearing, rock section. Then, inside the iron lining, concrete was inserted to the neat finished section adopted for the tunnel. This lined section remained in place in the finished work as an intermediate portion between two sections of cast-steel internal lining subsequently erected, which the following record describes.

The seams of greensand developed a maximum width of about 6 ft. at 3 750 ft. from the Astoria Shaft (Fig. 10). In this vicinity also, various pockets in the greensand seams were disclosed; one in particular being 4 ft. square and 20 ft. long, from which the previous water flows had evidently washed the sandy material.

On Plate XXIV, taken from the published Geological Survey, which presents the historical geology surrounding the Astoria Tunnel, it will be observed that there is a non-conformity in the plan defining the positions of the lines of contact as between the north and south sides of the Bronx Kills. This has been accounted for by assuming the existence of a cross-fault between Randall's Island and The Bronx, marking the course of the Bronx Kills. Although no conclusive evidence of the existence of such a cross-fault was observed during the driving of the tunnel, indications of its possible existence and proximity were observed. The material encountered in the vicinity of the assumed cross-fault was so disintegrated and decomposed, and the conditions for observations were so unfavorable, that it is doubtful if such a fault would be readily recognized in passing through it.

It has been assumed, however, that the tunnel passed through this hypothetical cross-fault, as shown on Plate XXVI, this assumption being based on two important facts:

1.—The distortion of the line of contact; and
2.—The rock structure encountered.

(1) It is quite natural that a cross-fault should have a limit of length, so that, in the case of this particular one, though it may extend through the Bronx Kills, as assumed, it may not necessarily extend to the path of the Astoria Tunnel. Such being the case, it seems possible that the actual fault at its eastern end terminates very close to the tunnel path, and that this end, instead of consisting of an abrupt fracture, is a gradual bend or distortion of the rock mass. That such a distortion was passed through is clearly shown on Plate XXVI. This distortion of the actual line of contact between the

hard micaceous gneiss on the west and the badly decomposed dolomite on the east, was encountered by an abrupt bend, 858 ft. from the center of the Bronx Shaft, and extended along the tunnel line some 70 ft. The maximum distortion was 10 ft., at a point midway along its length, at which point the hypothetical cross-fault has been assumed.

(2) The rock structure encountered at this point (893 ft. from the center of the Bronx Shaft), in addition to being extremely porous, was greatly shattered, more so than at any other point in the tunnel. The dolomite, especially, appeared like a mosaic of inlaid tile slabs, quite small (3 to 4 sq. in.), and readily removed by hand, although the individual pieces were moderately hard. It was at this place (Fig. 11) that three large water-flows burst forth at various times. One was an average single flow of 1 000 gal. per min., and in addition to this water, it carried in sediment large quantities of greensand and countless hard rock fragments. Here, too, it was necessary to terminate two heading drifts from the Bronx end. To the north of the assumed cross-fault, the actual contact between the gneiss and dolomite consisted of a continuous small seam, ¼ in. wide, of soft brown mud, and to the south of this point the contact plane was featured by a 3 to 4-ft. seam of hard, firm, bluish-green clay.

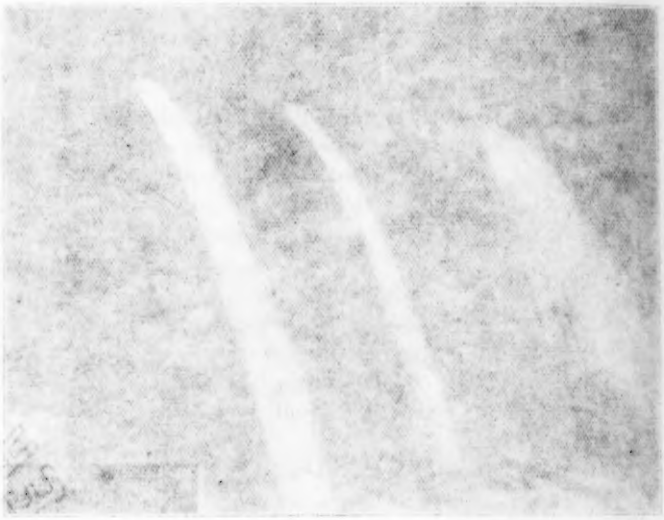
In this section of New York City, observation has established the existence of cross-faults, one at 138th Street and St. Nicholas Avenue, and one parallel to it, south of Hell Gate, and crossing the East River north of Blackwell's Island.

Water Flows.—The water-bearing fissures in the 354 ft. of decomposed dolomite were quite numerous, sixteen appreciable streams, each averaging from 300 to 10 000 gal. per min., under a full pressure head of 95 lb., having been encountered. These flows were usually quite sudden, and were accompanied by an inrush of greensand, the maximum flow of 10 000 gal. alone washing in 400 cu. yd. of sand, coal, etc., and, during a period of 6 weeks, some 1 700 cu. yd. of sand were washed into the Astoria heading. The establishment of a direct connection to the river bed was proved by the appearance of air bubbles on the river surface during grouting operations in the headings, as well as by the quantities of coal, wood, shells, bricks, etc., washed in at various times.

Method of Attack.—On account of the great depth of the tunnel and the resultant pressure head (95 lb. per sq. in.), any compressed-air methods of attack were out of the question, and, on account of the

FIG. 11.—WATER FLOW IN DRIFT AT STATION 37 + 71.

FIG. 12.—GROUT PIPES, STATION 38 + 55 TO STATION 39 + 00.



necessities of the gas supply, it was not desired to go to any lower level in an attempt to pass under the disintegrated bed of dolomite. It was consequently necessary to drive the tunnel at the original depth and alignment, so that the proposition presented was a difficult one.

The theory on which tunneling operations were executed through the decomposed rock formation was the thorough exploration of the formations ahead by test holes and the consolidation of the rock by grouting. It was very obvious, in working in a narrow top heading, even by drilling numerous holes in the form of a fan, that a very limited area could be reached for consolidation, and as the percussion drill, working on more or less horizontal or dry holes, is only capable of extending to a depth of about 20 ft., the tunnel section which it is possible to consolidate is very short, particularly in view of the fact that there is a definite limit to the number of grout holes which can be drilled into the face of such a small heading (Fig. 12), and that considerable time must be allowed for cement grout to attain strength to permit of blasting safely. It was obvious, therefore, that a greater area of attack must be provided, and this was done on the theory of diverting the heading from the straight line to lines external to the final side lines of the tunnel, following the line of the strike of the sound rock as far as possible to permit of cross access to the decomposed strata. By doing this a long face could be exposed from which the drilling could proceed. Further, whenever the rock was sound and reasonably hard, a full and adequate anchorage for the grout pipes was naturally provided, but, if the rock was decomposed, seamy, and water-bearing, it was usually found to be so soft that proper anchorage could not be obtained for the grout pipes. In such cases it became necessary to construct buttress faces to the soft rock after exposure, before grout pipe holes could be drilled and pipes inserted. The work was carried out on the further theory that grouting above the extrados of the arch and outside the side-walls, within the limit of the top heading, would in all reasonable probability cut off the direct access of heavy water flow and consequent danger of breaks occurring in the bottom. This was carried out to the end of the work and proved successful, as was illustrated by the fact that it was found unnecessary to do any grouting of considerable extent in order to take out the later bench excavation, the water-bearing seams having evidently been

plugged at the higher level and the resistance of the decomposed material in the seams being adequate to resist any indirect access or flow.

Reference has been made to the necessity for buttressing the face of soft rock to provide anchorage for grout pipes, in the event of the rock being unsound and not giving adequate security for the insertion of such pipes. In such cases, owing to the high pressures involved, these concrete buttresses were allowed to set for practically two weeks on each occasion before they could be utilized.

When such buttresses were set and thoroughly hard, or when sound rock existed, the process of preparing the grout pipes for use, as indicated by Fig. 13, was generally as follows:

The drilling was commenced with 6-in. percussion drills, and entered from 3 to 4 ft. deep into the concrete buttress or hard rock. A piece

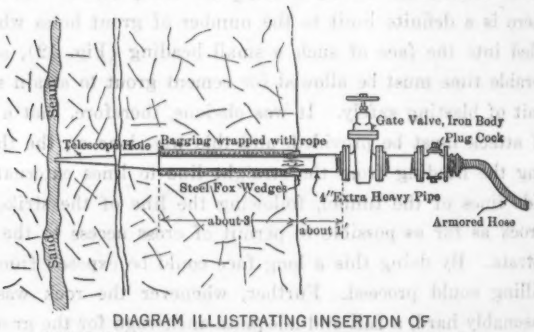


DIAGRAM ILLUSTRATING INSERTION OF GROUT PIPES IN ROCK FOR HIGH-PRESSURE GROUTING.

FIG. 13.

of 4-in. pipe, about 1 ft. longer that the depth of the hole, was then wrapped tightly with bagging and wound around with marline to secure it tightly to the pipe, the quantity of bagging being put on up to practically the dimensions of the 6-in. hole. The wrapped pipe was then inserted in the hole, and driven to its extreme end, no thread, flange, or other protector being put on the inner end of this first length of pipe. When thus inserted the wrapping was caulked back into the hole, and steel wedges were inserted and driven tightly between the 6-in. hole in the rock and the body of the 4-in. pipe. These wedges were driven so hard as to indent the 4-in. pipe and secure it rigidly. A screwed flange was then put on the outer end of this 4-in. nipple and an open gate-valve was attached to the flange, in order to provide

a clear opening equal to the diameter of the pipe. Drilling then proceeded through the gate-valve, commencing with 3-in. percussion drills and telescoping if necessary, as the drilling advanced. The length of the test holes rarely exceeded 20 ft. Of course, it will be understood that where the drilling was carried out from narrow cross-headings, and the holes were drilled at an angle with the strike, the effective length was reduced on account of the lack of clearance to insert long drills.

Reference is made in the following pages to the use of the diamond drill. On first meeting the decomposed rock at the Bronx end, a 1⅛-in. diamond drill was set up in the heading and holes were driven, one at the elevation of the heading, horizontally at right angles to the strike of the rock, in order to intercept the seams at right angles to the general strike; and two holes straight ahead on the axis of the tunnel, one horizontally and one pointing downward. The hole at right angles to the strike of the rock was extended in only some 50 ft., but the long holes ahead were extended for about 200 ft., and these drill holes gave an excellent idea regarding the conditions to be met, as far as drilling could be accomplished with the small machine used. At a later date, a heavier diamond drill, capable of drilling 3-in. holes, was used, and gave much more satisfactory results. The use of the diamond drill for long holes was extended considerably, previous to and after the flooding of the tunnel, giving long penetration and providing a means for grouting at considerable distances. The later diamond drill outfit was of the Sullivan type, of heavy construction, and proved to be admirably adapted to work of this character. In the entire construction through this decomposed rock section, some 3 300 test holes were drilled, aggregating a length of about 43 300 ft. by percussion drills, in addition to seventeen diamond drill borings aggregating a length of 1 500 ft.

Grouting in the Astoria Tunnel has probably exceeded very greatly that in any other work executed, in consolidating soft fissured rock, and in stopping extensive and large leaks at high pressure. Grouting at a higher pressure was done on the Catskill Aqueduct, though the volume of inflow was probably very much less. In the case of the Astoria Tunnel, the grouting was a continuous operation for consolidating and cementing decomposed rock throughout the entire length of the sheared contact between the gneiss and dolomite, and as such

served the purpose, a result which has not, it is thought, been approached or attempted in other work. The work involved was the conversion of a rotted and decomposed rock filled with fissures into a solid and substantial substance through which the tunnel could be driven and, incidentally, at the same time, stop the influx of water. In the grouting operations it was found to be almost impossible to grout into a seam of decomposed dolomite sand. This would apply equally to any other sand or material filling seams, which is likely to be scoured out by a flow of water. On meeting a seam filled with decomposed rock sand, the indications on this work were, that the sand was practically impervious, but, after a short exposure to water flow, the soft rock abutting on the seam became water-loaded and softened; then the passage of small quantities of water loosened and demoralized the sand filling the seams, following which the sand was scoured out, thus forming an open water channel. Therefore, it was found particularly desirable, after drilling grout holes into a seam filled with sand, to rake the sand out with rods, as far as was feasible, and then to allow these test holes to flow freely, by blowing with high-pressure air or in any other way, the idea being to get the sand to flow with the water and thus empty the seam, after which the grouting operation was much more thorough, successful, and permanent. When these seams were emptied of the sand and grouted at high pressure the result was practically a solid rock formation, and the tunnel could be built by blasting operations with security; whereas a seam not so clear of sand would resist the flow of grout and be a menace to the future advance of the tunneling operations.

Glass Tunnel Model.—In order to present clearly the actual geological information, disclosed both by direct observations and test-hole exploration, so as to determine the most advantageous direction of drift attack, an unusual method was designed by the field engineers and applied to this work. This consisted of a glass plate tunnel model. As the general strike of the rock containing the numerous seams of disintegration was nearly parallel to the tunnel line, and the dip was decidedly irregular, it was impracticable to plot the geological data on drawings and still have them clear and of working value, as they could not conveniently be superimposed. This condition was admirably simplified by this glass plate model, constructed at the tunnel works. This method of geological plotting proved quite successful, as

the conditions of the explored rock structure were clearly presented at a glance, proving an important factor in the determination of the various methods of attack adopted.

This model consisted of a series of glass plates, 16 in. square, placed upright in a skeleton frame, 12 ft. long, and arranged to scale corresponding to the 5-ft. tunnel stationing. As the tunnel driving proceeded, the actual lines, drifts, bulkheads, timbers, iron rings, etc., together with the exposed disintegrated seams and the test-hole information, were all painted with oil colors on the plates, this work being always maintained up to date, so that the conditions actually existing were always visible.

Blasting was naturally performed with very light charges, necessitated by the unsound strata, as water flows were easily started, not only by the shattering of the rock in their immediate vicinity, but by the concussions from blasting in sound rock at a considerable distance from the dangerous strata. In one instance, at the Astoria end, a 50-ft. length of drift was temporarily lost by this latter condition. The caution and care with which the rock was thoroughly sounded and scaled immediately following blasting is shown by the fact that no serious injuries or fatalities occurred, which is regarded as unusual, in view of the extremely unsound condition of the rock.

Grouting.—During the early stages of adverse tunneling, the grouting of the water-bearing fissures was performed with ordinary grout machines, using a neat Portland cement mortar at a pressure varying from 100 to 200 lb. per sq. in. This made it necessary, in September, 1911, to put in a steam-driven, straight-line booster at each plant. Grouting continued with this pressure for some months, but it became apparent as the work proceeded that an air pressure of even 200 lb. was insufficient to insure success.

For successful grouting into narrow seams it is essential to obtain a high initial velocity of grout flow, in order to overcome the frictional resistance; consequently, to grout against a water head of approximately 100 lb. per sq. in., more than 100 lb. additional pressure was found to be necessary. The increase of the starting pressure insured the initial flow, and the expansion of the air, even down to 200 lb. or less, was adequate to maintain the continuity of the flow. The use of the high pressure also insured that the seam would be packed

more tightly and that the grout would be more dense when it had taken its ultimate set and attained strength.

Consequently, an additional steam-driven straight-line booster was erected at the Astoria end in November, 1912, this machine being capable of developing an air pressure of 500 lb. per sq. in., for which special grout machines were constructed. The injection of cement into the water-bearing fissures at this pressure (500 lb.) was exceptionally effective, and was undoubtedly a valuable factor in the ultimate success in driving through the unsound water-bearing rock.

The disintegrated rock structure (Fig. 14) frequently necessitated the construction of concrete wall buttresses, in order to withstand the high grouting pressures used, and considerable difficulty was experienced during the early stages of the work in preventing the injected cement from washing out of the water-bearing crevices. Unsuccessful efforts were made to prevent this by mixing oats and bran with the cement mortar, as used in other subaqueous tunnels.

Another method introduced, which proved of great benefit and aided in securing the injected cement, consisted of the addition of a handful of fine-cut cotton waste to each batch of grout, which by fibrous reinforcement of the cement held it in place while it was setting. During lengthy grouting periods, two machines were used alternately in series, thereby maintaining a continuous injected flow.

The special machines for grouting with 500 lb. air pressure were designed and assembled at the tunnel works. The general arrangement and capacity were identical with the riveted pans for 200 lb. pressure, with the exception of some details designed to resist the higher pressure. The entire pan and the cover were made of cast steel, carefully annealed and tested, and having no joints other than that of the cover. The heads were made in convex form; one end was cast in one piece with the body, and the other was a cast-steel removable cover with male and female bolted flanged joints. In operation these pans were very reliable, and, when required, one pan was operated 25 hours without a stop, and discharged 4 500 bags of cement at pressures varying from 350 to 500 lb. Extra heavy 2-in. screwed pipe was used for the transmission of the high-pressure air from the engine-room to the heading, with the exception of the first 600 ft., where extra heavy 4-in. pipe was used to give greater storage capacity. Special 1-in. hose was used to make the connection between the air line

FIG. 14.—FACE OF HEADING AT STATION 36 + 72.5.

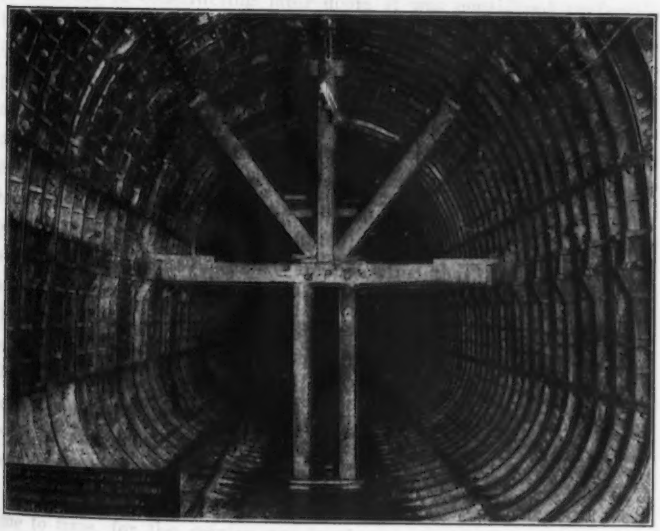

FIG. 15.—TIMBER BRACING BETWEEN BULKHEADS.

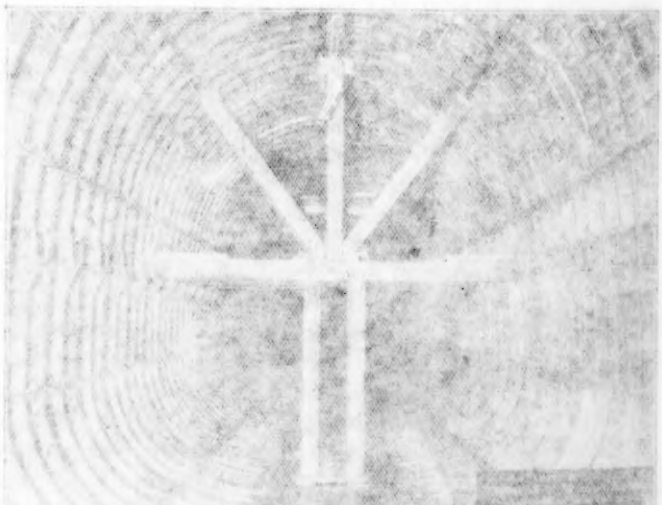

and the grout pan. This was a 6-ply rubber and canvas hose, with a marline woven cover, wound with $\frac{3}{16}$-in., half-round, steel wire, $\frac{4}{10}$-in. pitch. Knox standard couplings were fitted to each end. A special 2-in. grout hose was used, this also being of 6-ply rubber and canvas, wound with $\frac{3}{16}$-in., half-round wire, $\frac{1}{2}$-in. pitch.

Bulkheads.—Prior to entering the belt of disintegration at each end, adequate precaution was taken to guard against flooding, by the construction of full tunnel section emergency bulkheads, well back from the point of attack. As the headings proceeded, additional emergency bulkheads were built as close to the heading as the work permitted. These were to the heading size only, as the bench was not removed through this soft-ground section until after the meeting of the headings.

The first emergency bulkhead of full tunnel section, built at the Bronx end, was of a concrete buttress type, fitted with two guillotine doors and not reinforced. A guillotine type of door was considered in the first design to be the most certain in action. The clear openings of these doors were about 5 ft. square, of such size as to permit a tunnel car to pass through. These doors were never actually closed or used, but in constructing later doors it was considered preferable to adopt a simpler form of top-hinged flap, so that, in case of necessity, by cutting away the wire rope supports, they would drop readily into position, this type being not only cheaper to build but simpler in operation, and throughout the remainder of the work such doors were used. Some of the full tunnel section bulkheads, as well as the emergency bulkheads, were reinforced and some were not, the design being modified for each individual case. These doors were used only occasionally, and, as hereinafter stated, gave excellent results in operation. Owing to the necessity for knowing that these doors were always in working order, and for trying them out from time to time, they were equipped on the outer side with tripping devices and rams operated by compressed air from the tunnel line for raising them when they were desired to be opened. Valve arrangements were provided so that the door could be operated from inside or outside; thus, in the event of any one being accidentally left on the wrong side, it was possible for him to open the door and release himself.

Numerous solid heading and wall buttresses were constructed from time to time, for the reasons previously stated. This concreting, of

course, necessitated frequent and unusual delays, the accumulated lost time incurred by this work accounting for at least 50% of the time required to tunnel the 354 ft. of unsound rock, as generally from 10 to 14 days were allowed for the concrete to set sufficiently for 500 lb. grouting pressure.

During the bench removal, after holing through the headings, full section tunnel emergency bulkheads were necessary, these being generally about 14 ft. thick. As the bench excavation proceeded, these bulkheads were kept fairly close to the point of work, in order to facilitate transportation. The continual construction of heavy timber runways was necessitated by the fact that it was desirable to place the emergency bulkhead doors well above the invert, in order to prevent them from becoming clogged by the sandy sediment in the inflowing water. Drainage through the bulkheads was provided by 6 and 8-in. pipes, passing below the doorways, but at a sufficient height from the bottom to prevent them from being clogged by the sand. These drains were equipped on the shaft side with standard gate-valves to permit of their being closed.

Bench Excavation.—After the meeting of the headings, on July 17th, 1913, efforts were concentrated on the removal of the remaining bench, which, at that time, amounted to 474 lin. ft. This length of excavation was attacked simultaneously from the Astoria and Bronx sides. In the first 237 ft. on the Astoria side only good sound dolomite was encountered, no trouble was experienced, and the immediate lining of this excavation was not necessary. On the Bronx side the lower west portion of the bench face consisted of hard sound gneiss with intrusions of clay at its contact with the dolomite on the east. The dolomite was both porous and disintegrated, but no serious difficulties were encountered, although it was essential to place the concrete lining immediately after each short advance of excavation.

In this bench excavation the advance was thoroughly explored with long test holes ranging well outside the necessary excavation lines, and the material was displaced by light blasting. This arrangement was due, not only to the character of the rock, but on account of the existence of the overlying concrete arch.

The work proceeded in this manner until exploratory test holes disclosed the presence of excessive water at the Astoria side of the remaining bench. This water was located by four test holes, 3 ft.

apart, along the west side of the bench top. The nearest hole was 24 ft. from the bench face, and the total flow at high pressure was about 1 500 gal. per min. These holes were piped for grouting, and encased in an inclined concrete buttress, 20 ft. long and extending from the arch haunch to the rock bench.

The water was allowed to flow freely through these holes for one week, while the concrete buttress was attaining strength. The valves of the drains through the inclined buttress were then closed in preparation for grouting, and water broke through the top of the bench at the toe of the buttress. It was then decided to place a full-section emergency bulkhead at each end of this remaining 122-ft. section of bench, so that any water that might overcome working operations could be confined between the bulkheads.

On the completion of these emergency bulkheads, on September 16th, the work of preparing to consolidate the rock previous to excavation was resumed. The inclined buttress was removed and a much heavier and more massive one was constructed. This extended along 34 ft. of the bench top from the recently constructed emergency bulkhead on the Astoria side, was about 6 ft. high and 12 ft. thick, and was completed on September 25th.

At the same time, the western side of the bench top, at the Bronx side, was covered with a 23-ft. length of inclined buttress against the concrete arch and extending from the recently constructed Bronx emergency bulkhead to a heading emergency bulkhead on top of the bench placed during the driving of the Astoria heading. A similar inclined buttress, 13 ft. long, was placed against the west side of the arch. Thus, the entire 122 ft. of exposed bench was covered on the west side by a series of concrete bulkheads and buttresses.

After allowing these structures to set until October 1st, grouting through them into the rock fissures began, and 139 bags of cement were successfully injected into the last two mentioned buttresses. The grouting of the massive 34-ft. buttress was not successful, as the reactive pressure developed by the closing of the drain valves fractured this concrete structure very badly and rendered it useless for the purpose for which it was intended.

It was then decided to remove this fractured buttress entirely and replace it with one in the form of an inverted arch, and of more massive proportions, the inverted arch to react against the permanent roof

arch already in place. In the removal of this buttress blasting was done with extremely light charges, and every care was taken not to disturb the underlying rock bench. The removal of this buttress was completed about 8 A. M., on Sunday, October 5th, 1913.

7.—Flooding of Tunnel.

Shortly after 8 A. M. a large flow of water, carrying greensand, burst forth under high pressure from the top of the rock bench about 15 ft. from the Astoria emergency bulkhead. After flowing 30 min. the flow abruptly ceased, only to burst forth again a few minutes later with renewed vigor, yielding a volume of approximately 10 000 gal. per min., which eventually overcame the capacity of the pumps at the Astoria end. The bulkhead doors were promptly closed. On the Bronx side the force of the water was broken by the intervening heading bulkhead still in place, and the workmen were able to close the drains; but, on the Astoria side, owing to the rush of water and sand, they were able to close only two of the three drain valves in the bulkhead. It was found later that a small piece of 1-in. board, floating in the water, had become wedged between the door and the door frame of the bulkhead on the Astoria side. Through the small opening thus caused, and through the drain pipe which the men had been unable to close, the water poured into the tunnel, carrying with it a large volume of dolomitic sand and débris. The water in the Astoria Shaft rose steadily until, at 3.15 P. M., it had completely submerged the pumps, which soon thereafter ceased working, and the water reached tidal elevation at 8.15 P. M., on Monday, October 6th. At this time the pumping plant at the Astoria Shaft consisted of 12 pumps with a rated capacity of 7 500 gal. per min., but, on account of the sandy water continually handled, it had previously been found that the actual discharges were about 70% of the rated capacity; thus the actual capacity probably did not exceed 5 500 gal. per min.

Immediately following the flooding of the Astoria end, the Bronx emergency bulkhead was strengthened as a further measure of safety by a reinforced central buttress. On the completion of this buttress, an additional emergency bulkhead was built about 105 ft. nearer the Bronx Shaft. The actual need of this bulkhead never arose, as the first one withstood the full hydrostatic pressure, but it was desired to take every possible precaution against the flooding of the remaining

protected tunnel, as the unwatering of an entirely flooded tunnel would have been a much more difficult and costly proposition.

It was also considered advisable to increase immediately the Bronx pumping plant, which at this time consisted of five pumps with a rated capacity of 2 250 gal. per min., of which only 1 200 gal. capacity was available for shaft discharge to the surface, the remainder handling the drainage from the bench face to the shaft, as the grade at the Bronx end was away from the shaft. Four additional pumps, each having a capacity of 600 gal. per min., were put in, by which the capacity of the tunnel drainage to the shaft was increased to 1 650 gal. per min.; and the surface discharge capacity was raised to 3 000 gal. per min. This plant was fully capable of handling all the subsequent water from the Bronx end.

8.—Recovery of Tunnel.

Observations of the rise of water in the Astoria Shaft were carefully made, and also the tidal readings during the continuance of the shaft inundation. It was observed that the water rose and fell with the tide, but that the entire tidal rise was not obtained, the rise in the shaft being only about one-half that in the river. From the continuance of these conditions, and also from the flow obtained through small pipes in the Bronx bulkhead, it was apparent that the water flow had not choked itself as had been hoped. After due consideration of various methods of attack, it was decided to grout from the Bronx end into the water-filled chamber between the Astoria and Bronx bulkheads, with the object of filling this with cement to the extent of permitting the unwatering of the tunnel from the Astoria end. At the same time diamond-drill borings were to be driven from the Bronx bulkhead, the purpose of which was to intercept the fissure at a point beyond its opening into the tunnel, carefully calculated and directed to the desired point, and through this to inject cement, in an effort to seal the source of flow beyond the tunnel. The first hole drilled was intended to tap the fissure at a point 5 ft. below and 5 ft. beyond the point of flow into the tunnel, this location being determined by a close study of the geological formation previously encountered. This hole measured 120 ft. from the bulkhead face to the point. The accuracy of both the location and pointing of this hole was conclusively proved, not only by the injection of 870 bags of cement, but by the conditions

disclosed when driving through this section in February, 1914. The grout in this instance was evidently well directed into the fissure, but naturally followed the line of least resistance, going no farther than the débris in the fissure would permit.

The second step in the programme of attack was to fill completely the space between the completed arch and the rock bench between the bulkheads, and began by drilling through the Bronx bulkhead and the small disused heading bulkhead with a diamond drill, using a packing tube fitted with an exterior valve inserted in the bulkhead, through which the diamond drill rods were threaded and operated. These drill rods were pushed into the chamber as near as possible to the fissure location. Grouting through this diamond-drill tube began at 3 P. M., on November 10th, and continued without interruption until 4 P. M., on November 12th, during which time 8 580 bags of cement were injected at a pressure of 400 lb. per sq. in. The drill head, fitted with its diamonds, was recovered later from the mass of cement grout during the subsequent excavation. The grouting was discontinued on the appearance of cement in the seepage around the Bronx bulkhead door.

From the action of the water in the Astoria Shaft, it was quite evident that this grouting had been effective in sealing, to a large degree, the direct passage and subsequent leak between the tunnel and the river, but had not entirely sealed the leak through the Astoria bulkhead, as the draining of water through numerous small pipes in the Bronx bulkhead lowered the water in the Astoria Shaft some 17 ft. This water receding in the Astoria Shaft, and its subsequent loss of pressure head, resulted in an unequal condition of pressures on the freshly injected grout in the fissure, so that, when an absolute pressure of 11 lb. existed on the fresh grout, from the drop in the Astoria shaft water, the grout gave way, causing the water from the fissure to flow again into the tunnel, and the shaft water to rise.

Meanwhile, the long tubing was kept free, both inside and outside, and was withdrawn for this purpose to within 7 ft. of the inner bulkhead wall. It was again pushed forward in the early morning of November 14th, and 775 bags of cement were injected. Later the same morning, 622 bags were injected, followed in the afternoon by 986 bags. On the following morning 316 bags were injected, when the pressure gauge on a pipe extending through the bulkhead began to

jump in excess of the hydrostatic pressure, and, as grout began to appear through the bulkhead pipes, the operations were discontinued. Again, however, on November 17th, an additional 164 bags were injected through this tube, making a total of 11 342 bags of cement.

Meanwhile, the diamond drill borings had been continued, and, although water and greensand were encountered, only a small quantity of cement could be injected. It was evident, later, on removing this piece of bench, that the fissure in question was pierced only by the first drill hole. By opening the various pipes in the Bronx bulkhead, in order to test the hydrostatic pressure and to ascertain the effect of the grouting, it was found that they gave water, but without pressure, and, therefore, it was considered quite safe to commence immediately the unwatering of the tunnel from the Astoria end.

The consideration of the various possible alternative methods for unwatering the tunnel contemplated in every case the ability to hold the Bronx tunnel intact up to the emergency bulkhead, and the method adopted and subsequently carried out was based on that understanding. However, it was also considered as a possibility that this method might not prove successful in stopping the open leak from the river so as to enable a battery of pumps, which could be practically erected, to control the flow. As the heading had been entirely carried through and the test borings had defined quite clearly the position of the seams, it was thought that, if the plan of drilling with diamond drills, as previously described, and grouting through the diamond drill holes, did not prove successful, another alternative would still remain, by which a steel trestle could be erected over the tunnel on the bed of the river and from the deck of such a trestle, above high-tide level, numerous drill holes could be accurately placed and extended vertically to intercept the line of the seam, and through such drill holes grouting could be executed at any pressure desired, which would be amply adequate to fill the seam and plug it effectively. Fortunately, this last expedient was not found necessary.

Unwatering.—Existing in the Astoria shaft prior to the flooding were an 18-in. ventilating pipe (extending from the surface, down the shaft, and into the tunnel a distance of 970 ft.), and three 8-in. discharge lines (extending from the pumps at the foot of the shaft to the surface). These four pipes were converted into a pneumatic water-lift system by placing a 3-in. air pipe inside the 18-in. ventilating pipe,

extending the former to a depth of 251 ft. below the ground surface, or a depth of 240 ft. below mean sea level, and by placing a 2-in. air pipe inside each of the 8-in. lines to the same depth. The discharge ends of these air lines, for some 24 in. in length, were perforated with small holes drilled at an angle of 45°, so that the air discharge would point upward. These air lifts all discharged at the shaft surface. This emergency equipment was the only means used to lower the water 176 ft. from the top of the shaft, and down to that depth, proved both rapid and effective.

During the operations at the Bronx end, an emergency plant had been secured and prepared for operation at the Astoria Shaft. This consisted of six Cameron reciprocating pumps (one of 1 000, one of 800, and four of 600 gal. per min., a combined rated capacity of 4 200 gal. per min.). On a steel pontoon, designed and constructed specially for the purpose, and floating in the shaft, were placed the two emergency pumps (of 1 000 and 800 gal. per min.) with the discharge connected to an 8-in. discharge line in the shaft. Three 600-gal. pumps were placed in the elevator wells after the water had been lowered 172 ft. below mean sea level. These pumps were lowered from time to time as the water dropped, and, when it had been lowered to a level of 13½ ft. above the tunnel invert at the shaft, the submerged permanent pumps were brought into play.

The 18-in. and two of the 8-in. air lifts were operated continuously from 8 A. M. to 9 P. M., on November 24th, when the water had been lowered a depth of 160 ft., displacing 1 147 028 gal. of water in 797 min., or an average discharge of 1 439 gal. per min. The two pumps on the pontoon were then started and worked continuously until 6 A. M., on November 25th, with a net gain of 15 ft. The three pumps in the cage wells were then operated, it being necessary to change the pipe-line connections quite frequently. On November 30th, at 10.40 A. M., the water had been lowered to a level 13½ ft. above the tunnel invert at the shaft portal. During the progress of this stage of the pumping, in order to avoid a column of water forming at the Astoria bulkhead and a consequent probable regurgitation of the water in the shaft, air under pressure was forced into the tunnel through a 2-in. pipe, which was in place and extended from the surface about 3 200 ft. into the tunnel. At 10.40 A. M., on November 30th, the original shaft pumps were started, and, as this gave in all a battery of eleven pumps, the

water was quickly drained from the tunnel. During the period occupied in pumping at the Astoria end, a 2-in. and a 5-in. pipe in the Bronx bulkhead were kept flowing, and materially aided in the unwatering. Table 6 is a summary of the water pumped and the time occupied.

TABLE 6.—SUMMARY OF WATER PUMPED, ETC.

AIR LIFTS—ASTORIA END:	
Time worked	13 hours 17 min.
Volume of shaft unwatered	1 147 028 gal.
Average per minute	1 439 gal.
PUMPS—ASTORIA END:	
Time worked	162 hours 53 min.
Volume of shaft and tunnel unwatered	8 415 353 gal.
Leakage into tunnel	15 608 873 gal.
Total water pumped	24 024 231 gal.
Average per minute	2 458 gal.
AVERAGE LEAKAGE INTO TUNNEL THROUGH THE FISSURE DURING THE PERIOD OF UNWATERING:	
Flow through pipes, Bronx bulkhead	938 gal. per min.
Leakage through Astoria bulkhead	997 " " "
Average leakage through fissure	1 935 " " "
Period of unwatering approximately 25 000 000 gal.	7½ days.

On Sunday evening, November 30th, with the water 4½ ft. below the crown of the arch at the portal, two boats containing the tunnel engineers entered the tunnel and continued on a tour of inspection to the Astoria bulkhead. It was found that comparatively little damage had been done by the flooding, although a considerable quantity of grout and sand had entered the tunnel through the door which, in the inception of the flood, was not securely closed, and through the 8-in. drain which the men had been unable to close, as previously mentioned. Sand deposits occurred at frequent intervals throughout the first 2 300 ft., and beyond this a layer of sand, mud, coal, shells, etc., covered the tunnel invert, accumulating in quantity toward the bulkhead. At a distance of 3 000 ft. from the shaft, the grout, with a small proportion of sand, formed a bank 12 in. deep, gradually sloping up to the bulkhead, a length of about 500 ft., where it was 12 ft. thick, or nearly to the top of the bulkhead doorway. The surface of this grout bank was in a plastic condition, some 6 in. deep, the underlying material being firm and semi-hard, the hardness increasing toward the bulkhead. This material was not well set-up grout by any means, the subsequent removal being performed with pick and shovel. From the 8-in. drain clear water, at the rate of 900 gal. per min., was flowing, and from a 3-in. cable conduit pipe in the bulkhead there was a stream

of 100 gal. per min.—neither being under pressure. The air throughout the tunnel was exceptionally good.

The construction of an emergency bulkhead about 60 ft. from the closed bulkhead was immediately commenced, before making any attempt to remove the aforesaid grout bank, as the appearance and condition of the grout bank material were such as to cause very grave doubt that the leak would remain confined. A small trench was excavated in the grout bank around the bulkhead drains; the two closed ones were blind-flanged and the open one was allowed to flow, in order to prevent the development of any additional pressure on the bulkhead.

Simultaneously with the construction of the emergency bulkhead, the cleaning and righting of the tunnel proceeded. Meanwhile, the emergency pumps were erected at the shaft bottom and the original pumps were overhauled. When this work was completed the Astoria plant consisted of fifteen pumps, with a combined rated capacity of 9 600 gal. per min., which was considered quite sufficient to handle any likely flow, in view of the existence of an additional bulkhead removed from the point of danger.

The method of procedure adopted for completely sealing the water flow of October 5th consisted in driving a series of long test holes, in an effort to pierce the fissure well outside of the tunnel lines, through which the effective seal and solidification of the rock mass would be obtained by injecting grout. The short holes were drilled with percussion drills and the long ones with diamond drill equipment through the tunnel side-walls close to the bulkhead, as it was desired not to disturb the latter in any way. The direction of these holes was based on the assumption that the water-bearing fissure would be encountered in a plane produced along the line of the general strike of the rock and passing through the ends of the holes by which the presence of the fissure was first determined prior to the flood. The first hole drilled with a percussion drill to the computed depth, encountered water at full pressure at a depth of 22 ft.; the success of this hole was very encouraging, as it had been computed that water would be encountered at 21½ ft.

The observation of results attained in grouting was accomplished by the attachment of pressure gauges on both the Astoria and Bronx bulkheads and by allowing the pipes in the Bronx end to remain flowing. Grouting began at 1 P. M. on December 18th, and was followed

immediately by the appearance of grout in the flowing Bronx pipes, thus indicating that the point of injection communicated to the water hole of October 5th, and that the latter was still unsealed. At 9 P. M. on December 19th, after the injection of 3 360 bags of cement, the hole finally refused.

It was quite apparent that the recent grouting had been effective, but, during the time interval necessary to allow this to set thoroughly, it was decided to make a thorough investigation of the underlying rock before attempting to open up the grout-filled chamber between the bulkheads. This investigation proceeded during the remainder of December, and consisted of drilling ten long diamond drill holes, the result being that, though the rock structure outside the tunnel lines was found to be extremely disintegrated, no water was encountered—a favorable indication of the success of the recent grouting.

On January 5th, 1914, the work of removing the grout fill between the bulkheads commenced. A small drift was driven through the Astoria bulkhead, after which the door was raised and immediately placed in working order. The removal of the grout fill was then resumed, this work proceeding with very light blasting, toward the Bronx bulkhead door, which was raised on January 15th, 1914, and preparations were made for resuming the bench excavation—after a delay of 102 days, caused by the flooding of the tunnel.

In removing the grout fill, it was found to be in an unusual condition and stratification. Certain layers were extremely hard, and others were equally soft; some sections were highly stratified—others quite massive; some layers and masses of what might be described as solidified "laitance" were found, which never attained a greater hardness than that of the softest chalk, and having a curious chemical composition, entirely different from that of the original Portland cement from which it had been produced. Layers of sand also extended through the mass, and, in the vicinity of the water-hole, a 4-ft. blanket of coal, sand, shells, bits of wood, etc., was disclosed. No indications of water were apparent, other than the usual normal seepage through the concrete lining.

Several interesting conditions were encountered during the recovery of the flooded tunnel. Although large quantities of sand, coal, bits of wood, etc., were found, having been washed into the tunnel, and thus establishing proof of a direct connection with the river bed, no signs

of any fish were observed, though during previous heading flows many live fish, up to 8 in. in length, were washed in.

Of unusual interest is the fact that, though the sum total of cement injected from both ends, from the time of the flood to the completion of the grouting, was only 595 cu. yd., about 1 150 cu. yd. of solid grout were removed, in addition to 400 cu. yd. of sand, shells, coal, etc., to say nothing of the quantity of cement grout which remained in and filled the fissures themselves. A possible explanation of this is that in some manner the injected cement had mixed freely with very fine-grained decomposed dolomite, probably in sediment in the water, and that cement in the form of grout does not act as normal Portland cement in maintaining constant volume.

A peculiar disclosure was made on uncovering the end of the long grouting tube inserted from the Bronx end. The end of this tube was solidly embedded in a 12-in. cube of extremely hard grout, entirely surrounded by a 4-ft. layer of sand, coal, shells, etc., thus isolated from the bulk of the grout in the chamber between the bulkheads. Apparently, with each injection, the cement scoured away and was forced through this sand layer, which then resumed its normal form after each discharge.

In view of the recent flooding, it was resolved to exercise even greater precautions than heretofore. After careful consideration, a method of attack was devised which ultimately proved quite successful. This consisted of: (*a*) the construction of an inverted concrete arch over the remaining length of bench between bulkheads; (*b*) an even more thorough exploration of the underlying rocks with test holes as long as could be drilled by percussion drills; (*c*) the injection of cement through these holes in an effort to solidify the rock mass—the inverted arch acting as a resistance to this grouting; (*d*) the careful excavation of the exposed rock by very light blasting of small sections only; and (*e*) the immediate concreting of the tunnel lining on completing a short length of full section excavation.

The inverted arch was 24 in. thick and 8½ ft. below the concrete tunnel arch on the center line. As this working space did not permit of drilling to the tunnel invert extrados, the exploration was accomplished by first testing to a depth of from 5 to 6 ft. below the inverted arch. Drilling pits were then excavated and concrete-lined as an inverted arch, well bonded into the tunnel arch and the inverted arch

slab. Test drilling was then continued from these pits, thus reaching well outside of the necessary lines of excavation.

In removing this 122 ft. of bench, the entire rock encountered was extremely wet, and, although two flows of fair volume occurred, no unusual difficulties were experienced. This was undoubtedly due to the numerous injections of grout, which had been quite effective in consolidating the disintegrated rock structure. On uncovering the water-hole of October 5th, it was found to be a greensand seam, 24 in. wide, and of unknown depth, filled with sand, coal, shells, etc., through which a 9-in. layer of hard grout extended. No water was flowing, nor was there any further trouble from this fissure.

9.—Steel Lining.

Following the completion of the bench excavation, the erection of the cast-steel ring lining began. The installation of this lining was to secure impermeability through some 400 ft. of wet rock section extending on each side of the existing 50-ft. length of cast-iron rings. Being an after consideration, it was of necessity devised for its adaptability to the existing conditions. In contrast to the 50-ft. section of iron lined tunnel, the rock structure of the zone finally lined with steel rings was of such poor quality, and so treacherous and shattered, that it would have been extremely hazardous to increase the area of excavation necessary for the insertion of circular rings. Therefore, it was desired to maintain as small an excavated section as possible, and this resulted in the adoption of a metal lining of special design.

The usual assumption in designing a metal lining for subaqueous tunnel construction is that it is surrounded by a more or less plastic medium, and that no inward collapse can occur at any point without an outward distortion taking place at other points on the periphery; usually, the most suitable section to meet these conditions is a circular one. In this case, however, the tunnel being deeply embedded in rock and of a horse-shoe section, there were certain assumptions which could not be made in the case of a tunnel surrounded by soft material without cohesion. That is to say, the assumption on which the tunnel lining was designed was that, on the completion of the work, the spaces between the metal lining and the rock would be solidly filled with concrete or cement grout, which, when placed, would support

the entire metal lining and prevent any possibility of an outward distortion of the lining, the latter being designed with sufficient strength to prevent any inward collapse.

However, partly on account of the hydrostatic pressure, and partly on account of the departure from a true circular form, such stresses were produced in the metal that, without an extraordinarily wasteful design, cast iron could not be considered as a feasible material for withstanding the resultant pressures, and it appeared, therefore, to be necessary to substitute cast steel.

The cast-steel segments used for this purpose were made by the Wheeling Mold and Foundry Company, in accordance with the specifications of the American Society for Testing Materials. The segments were machined on all flanges to exact templates, so that all segments of the same letter were interchangeable. The facing of all joints of the steel segmental plates was laid out from the templates, which, at the same time, defined exactly the position of coupling bolt holes, which holes were drilled in the plate castings. Although the specifications permitted the use of cored bolt-holes, no such coring was used on account of the impossibility of obtaining the accurate fitting of segments with the irregularities which would have thereby been caused, the specifications requiring that this absolute accuracy of segment form in its relation to the bolt centers should be maintained.

This cast-steel lining, Fig. 16, was of segmental form, shaped to the neat lines of the tunnel, with the extrados 7 in. beyond these lines. As the flange depth of the rings was 6 in., and it was not desired to increase this depth at the expense of cutting away more of the exterior concrete lining, there was an allowance of only 1 in. of concrete over the ring flanges in covering the lower segments up to the springing line of the arch, being simply a protection against possible corrosion and to produce a continuously fair and smooth surface for the interior of the tunnel.

Each ring consisted of eleven segments, including the key; all joints were accurately machined. The key was placed at the top, and the joints were not staggered, as is the custom with circular iron tunnel rings. The rings were 24½ in. wide, this odd width being designed on the assumption that a slight excess in the gauge length of each ring would be probable, and that in erection a growth or

FIG. 16.

creep of ¼ in. to every six rings would occur. Actually, the machining was executed with almost perfect accuracy, and in erection no creep resulted throughout the entire length of 400 ft. Each segment, excepting the key, was provided with a tapped hole for grouting behind the rings, and each ring was equipped with brackets cast on the side plates, to carry a transverse 10-in., 40-lb., beam for the support of the permanent tunnel runway, and also to act as an additional strut to react against any possible horizontal distortion of the rings.

In consideration of the possible danger of causing serious water flows by the removal of the concrete lining necessary for the erection of the steel lining, it was decided to perform this trimming without the use of blasting but by taking off the necessary 9 in. by bull-pointing with small air-driven jack-hammers. For this same reason, a special method of procedure in erecting the steel was adopted. This consisted in erecting the 200 rings in four sections, by which arrangement, and the construction of two emergency bulkheads, the point of work was always protected, so that any unusual flows could readily be confined to a comparatively small length of tunnel.

Previous to the erection of the internal steel lining, the rock tunnel had been secured by a concrete lining, at no point less than 18 in. in thickness, which concrete was adequate, as long as it remained in perfect condition, to take all the hydrostatic pressure strains. At the same time, the concrete was not impervious, and as water would pass through it into contact with the steel lining, it would obviously transmit hydrostatic pressure to that lining. Simultaneously with the excavation of the rock bench, the exterior concrete lining was put in, but, as the arch concrete had previously been placed to the finished tunnel lines during the driving of the headings, it was necessary to chip the entire inside surface to provide space in which to erect the steel lining to the true lines called for. Consequently, there was a very small space remaining between the intrados of the concrete lining and the extrados of the steel lining. It was of vital importance, on account of the accurate machining to templates, that the rings should be erected absolutely true to the axis, and the only way in which this could be done without any question of doubt was by erecting with absolute accuracy a long stretch of the bottom plates, bolted up and laid out instrumentally to perfect alignment and grade. In order to do this,

the bottom plates throughout were laid on a cradle consisting of three longitudinal strips of bar steel, 4 in. wide and ½ in. thick. These cradle bars were wedged up to proper alignment and grade, and secured by spiking with countersunk expansion bolts to the exterior concrete lining already in place. On this cradle were erected the two bottom segmental plates. The first short length of complete section lining, about 100 ft., was erected continuously on the bottom plates already set on the cradle, and each plate as erected was wedged with oak wedges to the exterior concrete lining already in place. The ends of this section were carefully secured by cementing, grouting, and packing, in order to maintain them rigidly and to plug the narrow spaces at each end, the theory then being to proceed with the grouting by leaving all grout holes open and pouring grout into each one in succession, and, as each hole indicated free flow of grout, to close each plug in its turn. It was thought that the plate lining, being held securely by hardwood wedges at each plate and the setting of the cement as grouting proceeded, would enable this section of steel to retain its form. Experience, however, showed that the hardwood wedges were inadequate to resist deformation in consequence of the pressures due to the flotation, and quite a serious distortion occurred in this section during the grouting operation, necessitating the entire removal of the section and its re-erection on the plan adopted later, as follows:

The rings were erected on the iron strip cradle previously described, on which the bottom plates for several ring lengths were first placed, followed by the same length of smaller radius side-wall plates. The remainder of each ring was then erected separately, this work being done by an erector. This method was adopted to prevent any divergence from alignment, as no special rings were provided to correct alignment deviation. The space behind each segmental joint was securely blocked with iron wedging to prevent distortion during the subsequent grouting operations. The method of grouting behind the rings consisted of forming a circumferential bulkhead of cement mortar behind two complete rings consisting of one whole and two half rings, spaced at a distance of five rings apart, and a longitudinal bulkhead behind the smaller radius side-wall plates, thus permitting grouting behind the rings in stages. This was essential to prevent distortion due to the weight of cement and the flotation of the

tunnel. To insure further against the possibility of distortion, the five-ring section between bulkheads was internally braced with heavy timbering (Fig. 15). Only one set of timbers was used, grouting operations being carried along in the rear of the erection at the same rate of progress in each. By this arrangement the five-ring sections were completely grouted before the removal of the timbering, the grouting being performed in three operations: first, the lower half above the longitudinal bulkhead; second, the upper half (thus keying in the top portion); and, third, the bottom plates. The first operation was with an air pressure of 30 lb.; the second and third were with 135 lb.

The rings were grommetted and caulked on the completion of the grouting. In grommetting, which was carried on immediately in advance of the caulking, each bolt was wrapped with strands of hemp, not coated with any water-proofing substance, as is usually the practice, as it was determined by experiment that the results derived from pitch-dipped hemp were not better than with the uncoated strands. In caulking the ring joints, small air-driven caulking hammers were used, the procedure consisting simply of turning over the metal edges of the joint, in every respect as though caulking a boiler. In unusually wet places lead wire was used to stop the flow temporarily until the edges were turned. This 400 ft. of steel lined tunnel is now practically water-tight, although occasional drops are caused by the natural sweating of the metal. This in time will probably gradually dry up and disappear entirely, due to the corrosion of the metal and the silting in of fine particles of matter.

10.—Drainage.

The completion of the tunnel with the entire lining left a seepage of water to be taken care of by the permanent drainage and the pumpage of 280 gal. per min., this seepage coming in from the entire length of the tunnel and the two shafts, including the enlargement at the foot of the Astoria Shaft. Consequently, this leakage was yielded by the equivalent of some 5 600 ft. of full-sized tunnel, or a surface area of approximately 36 000 sq. yd. This inflow for the most part finds its entry through the jointing of the rock in the hardest portions of the granitic gneiss, including the Astoria Shaft and the tunnel extending from that shaft to the dolomite rock con-

tact. The softer dolomite is, for all practical purposes, perfectly dry, and there is practically no water finding entry through the section lined with steel plates. The remainder of the inflow originates in the similar hard gneiss constituting the Bronx Shaft, and the section of the tunnel between the bulkhead line of the East River and the westerly contact.

The writer has invariably found that, so far as water flow through the rocks in the vicinity of New York is concerned, the greatest leakage is in the hardest rocks, and that wherever the mica schist or dolomite rocks exist, their softer character closes the joints and fissures to such an extent as to make these rocks practically water-tight.

Considerable efforts were spent on grouting through the lining to lessen the leakage from these hard rocks, including the drilling of long holes through the lining to intercept the minute joints and fissures, into which was forced cement grout under pressures of from 200 to 300 lb. per sq. in. For a time this would prove effective, but, within a few days after stopping the inflow, under these conditions, it would almost invariably be found that water would work its way through other channels, with the final result that the grouting of the rocks had little effect on the total quantity of water. There are indications, however, that in the course of time a great many of these minute fissures will choke themselves by the washing in of particles of solid matter to fill the crevices, a condition confirmed by observation of other tunnels.

11.—Ventilation.

The proper ventilation of the tunnel during the construction period was obtained with electrically-driven suction fans—one operated on the surface at each plant—capable of furnishing 2 500 cu. ft. of air per min. at a pressure of 5.4 oz. Each fan was at the top of each shaft, and was connected by a 12-in. inlet to an 18-in. pipe extended down the shaft and along the tunnel wall to within 200 ft. of the bench, sections being added as the advance proceeded. The fans were not operated continuously, but only until proper ventilation was secured after each blasting operation. On the Astoria side a 30-in. blower, driven by a compressed-air engine, was erected in the tunnel 1 700 ft. from the shaft, as the 12-in. fan was not efficient beyond this length. This blower was connected to the existing 18-in.

line from the 12-in. fan, the fan being discontinued when the blower was put in operation. In tunneling through the zone of decomposed dolomite, the construction of bulkheads close to the point of work in the heading naturally interfered with proper fresh air circulation, and at times the inflowing water carried with it sludge tar which had probably been discharged many years previously from adjacent gas-works and had been lying on the bed of the river in deep holes. This material gave off fumes which were unpleasant and caused a burning sensation in the eyes, but at no time during the work was there any illness or inconvenience attributable to improper ventilation.

12.—Lighting.

The tunnel was lighted electrically by current supplied at each plant by two direct-current generators, each of 250 volts, 200 amperes, and 50 kw. These were operated alternately, except at the Astoria end, where it was necessary to operate both generators at night after the tunnel had been driven 1 000 ft.

Lamps of 16 c.p. were used while in the heading and bench. Luminous-arc headlights were carried along with the advance, the result being very satisfactory, as these lamps gave a bright whitish light, quite essential through the dark, wet, rock sections, and especially in driving through some dense, black gneiss encountered. After entering the decomposed, water-bearing zone, kerosene hand-lanterns were used throughout the tunnel as a measure of safety, and were kept lighted at all times in case of emergency.

13.—Triangulation and Alignment.

The triangulation system of the Astoria Tunnel was first laid out in 1903-04, and conformed with the intentions at that time of constructing the tunnel to 111th Street, Manhattan. Subsequently, this triangulation system, with the necessary modifications, was adopted for the alignment of the present Astoria Tunnel.

The triangulation system of the present tunnel consisted of three scalene triangles constructed on an 1 800-ft. base line on the Astoria shore, with a 1 300-ft. check base on the Bronx shore, one angle point being on the extreme northerly end of the "Sunken Meadows" in the East River. The accuracy of the triangulation work was proved by the fact that the computed length of the Bronx base checked to within 0.006 ft. of the measured length, or 1 in 218 000.

The alignment was transferred down the shafts of the tunnel with suspended plumb lines which were aligned by direct sight across the river between shafts, triangulation towers being provided for this purpose. Some little difficulty was caused by the oscillation of the wires due to eddying air currents and the water seepage down the shaft sides, these conditions necessitating the use of 35-lb. wing weights. At the Astoria Shaft the base between the suspended wires was 28 ft.; in the smaller Bronx Shaft, the base was only 21 ft.

In the extension of the tunnel center line, all fixed points were placed in the concrete arch—those in the Astoria heading were at 300-ft. intervals, but in the Bronx heading a maximum of only 200 ft. could be used, on account of the continual fog. As the headings approached the water-bearing rock section, it was found necessary to reduce the sight lengths considerably, especially after the construction of bulkheads, as the fog then became, in a sense, confined. All instrument work was performed from suspended transit tables and scaffolds, thus preventing any delays to, or confusion between, the engineering and construction forces.

Accurate elevations were determined from a bench-mark on the northern shore of the Bronx Kills opposite Randalls Island. The reference of this bench-mark to a mean-sea-level datum plane was supplied to the tunnel engineers by the United States Coast and Geodetic Survey, being based on the result of 6 years of tidal observations at Sandy Hook, N. J. The location of this bench-mark necessitated a level run of 3 900 ft. to the Bronx Shaft and a run of 14 000 ft. to the Astoria Shaft, the latter route crossing Randalls and Wards Islands to reach the point of minimum width of the East Channel of the East River. Thus, the length of the combined transfer of elevations of 3½ miles on the surface to the point of closure in the tunnel was approximately 4½ miles, in view of which the error of only ⅛ in. is quite remarkable.

In consideration of the unfavorable conditions under which the underground work was necessarily performed, the meeting of the alignment and grades of the two headings is regarded as most satisfactory. As mentioned, when the tunnel entered the water-bearing rock, there was considerable difficulty in obtaining even fairly distinct sights, as there was a continual fog caused by the condensation of the air exhaust from the drills, pumps, and grout pans. The alignment,

which was carried 3 900 ft. from the Astoria Shaft and 762 ft. from the Bronx Shaft, met to within 1¼ in. for line, ⅛ in. for grade, and ½ in. for stationing.

14.—Quantities and Costs.

Table 7 is a summation of the quantities incidental to the shaft and tunnel construction.

*Tons of 2 000 lb.

In this undertaking the cost of construction must be classed in two accounts: first, the cost of the shafts and tunnel constructed under normal conditions in the two types of rock formation; and, second, the extraordinary cost and expense of that portion of tunnel, approximately 400 lin. ft., constructed in the decomposed rock formation. The cost of the permanent pipes and interior equipment is an additional and entirely distinct item of expense, bearing no direct relation to the cost of the structure of the tunnel.

It is worthy of note that the unit costs, based on all work of a normal character, with the sole exception of the great expense of getting through the decomposed rock, was less than the originally estimated figures contemplated at the commencement of the work.

The unusual conditions involved in that portion of the tunnel driven through the decomposed rock formation, and the long delay in conquering the difficulties which arose, involved an actual cost for that section materially greater than had originally been allowed.

Tables 8 and 9, showing the distributed unit costs for the shaft and normal tunnel constructions, are of interest and value, and show advantageous results under the conditions governing the work. The unit costs given in these tables are the totals for both labor and material, allowing 60% of the purchase value of plant and equipment —the remainder being considered as a credit for ultimate salvage. The item "Contingencies" includes all expenses chargeable to accidents, damages, hospital, rentals, insurance, and operation of the ferry-boat used between the shafts.

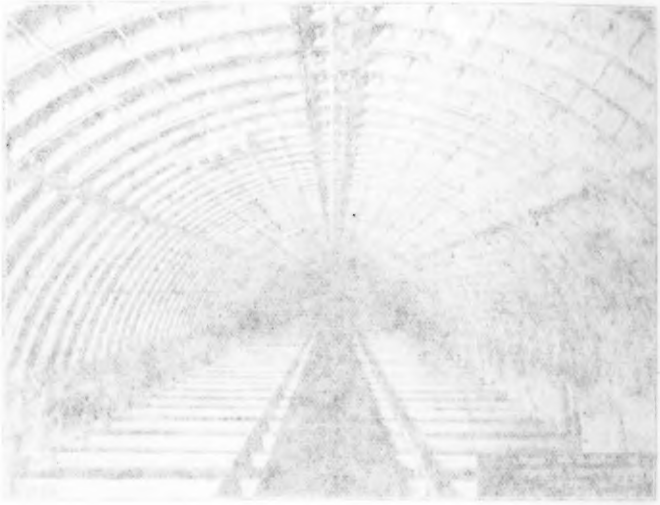
15.—CAST-IRON PIPES IN THE TUNNEL.

The cast-iron pipes in the tunnel from Astoria to The Bronx are the largest ever made. Their internal diameter is 72 in.; the thickness of metal in the pipe walls is 2¾ in.; they have hub and spigot joints, and were cast in standard 12-ft. lengths. The weight of each pipe is 26 000 lb., and the displacement of water by each length represents some 24 800 lb., from which it is seen that, even should the tunnel be allowed to fill with water, the pipes would retain their position secure.

These mains are arranged in two parallel lines occupying the lower portion of the tunnel, and are supported on concrete bed-blocks. The structural steel runway, Fig. 17, for supporting any future utilities that may be put in, extends through the tunnel and is just above the mains. The concrete blocks are 6 ft. apart, each block supporting

FIG. 17.—TUNNEL RUNWAY THROUGH CAST-STEEL RING SECTION.

FIG. 18.—LOWERING 72-IN. CAST-IRON T DOWN SHAFT.



both lines of pipe. Each 12-ft. length of pipe is supported by two blocks, and the joints of the two pipe lines are staggered. Every second block supports a cast-iron column which braces the center of the transverse runway beams, the actual support for the runway being provided by cast-iron brackets anchored to the concrete tunnel walls. In both shafts the two 72-in. pipe lines are connected to the tunnel lines by double-spigot eccentric reducers and bell-spigot bell tees. All the vertical risers are 12 ft. long, with both the spigots and bells machined on the face to take the true bearing of the vertical pressure loads. At the top of each shaft flanged spigot tees, reducing to 48 in. diameter, connect to 48-in. pipes through the shaft lining into concrete valve pits, thence passing underground—in Astoria to the gas holders, and in The Bronx to the street feeder lines. Each shaft is equipped with an elevator and an emergency ladder, the elevator framing also acting as a bracing for the pipe lines. The tunnel runway extends to the elevator landing at the bottom of each shaft, and in the Astoria Shaft there is an operating floor in the enlargement.

During the driving of the tunnel, arrangements proceeded for putting in the permanent piping, and consisted of unloading and storing the pipe and structural steel, casting the concrete pipe bed-blocks, setting bolts in the tunnel side-walls for the support of the tunnel runway, and the design and construction of additional plant equipment necessary in laying the pipe.

The pipes, excepting those for the Bronx Shaft, were stored at the Astoria plant, as the required space was available there and as it was also the intention to lay them from the Astoria side, this shaft affording the larger working area. The concrete blocks were cast on the surface at the Astoria plant, the work being completed fully a year before the pipe-laying commenced, so as to insure the maximum strength. Collapsible wooden moulds were used, and the mix was a rich gravel concrete, as it was desired to secure a thoroughly sound block. The blocks contained reinforcing rods, bolts for securing the runway columns, and small pipe holes to which the slugs were attached when lowering into the tunnel. As the saddles were long and of irregular shape, the reinforcing rods were necessary to prevent fracture due to their dead load when lifted by the derrick.

The permanent bracket bolts for the support of the tunnel runway are 12 ft. apart, and there are two bolts at each bracket; but, as it was

intended to use a traveling crane, running on steel girders secured to the tunnel walls, for which two bolts were insufficient, advantage was taken of the necessity of the permanent bracket bolts and the crane track design arranged to utilize those bolts. This resulted in placing four bolts at each bracket location. The bolts were 1¼ in. in diameter, 24 in. long, and were secured 18 in. in the concrete side-walls.

In laying out the bracket holes, the marking points were permanently secured, each consisting of a small nail driven into a wooden plug set in the concrete walls of the tunnel; thus the points were preserved until a year later, when they were used for spacing and grading the pipes. This simplified the necessary field engineering during the laying of the mains, and was a decided factor in the excellent progress attained.

The principal additions to the plant equipment, incidental to the laying of the 72-in. mains, consisted of a 50-ton steel derrick and engine, a traveling crane, and two pipe-testing machines.

The steel derrick for handling the 72-in. mains, Fig. 18, had a 50-ft. boom and a 35-ft. mast. Power was supplied by a steam-driven engine, having a 10-in. cylinder and a 13-in. stroke. The swinging gear was operated independently by a rotary engine. The hoisting rope was a six-part line of ¾-in. special wire cable, and the boom fall was a twelve-part line of ¾-in. wire cable. In operating this engine, the load was lowered by throwing the clutch into gear and allowing the engine to run backward, instead of throwing on the brakes, as the friction burned up the wooden brake bands too rapidly. This method was considerably safer, and gave better control, than by lowering with a brake. Special slings were constructed for handling one pipe and two saddles together.

The traveling crane, Figs. 19, 20, and 21—designed by Mr. Hodgson for handling and erecting the pipe within the tunnel—was constructed on a wood frame fitted with cast-steel wheels running on steel girders attached to the concrete tunnel walls by the 1¼-in. bolts previously mentioned. The wheel base of the crane was the same as the bracket spacing, so that the load on the bracket could not exceed the maximum wheel load of the crane, which was 15 000 lb. The crane was operated by two 5-h.p. air engines—one for the longitudinal and the other for the transverse movement. The speed was from 40 to 50 ft. per min., quite sufficient for the short distance covered. Each end of the crane

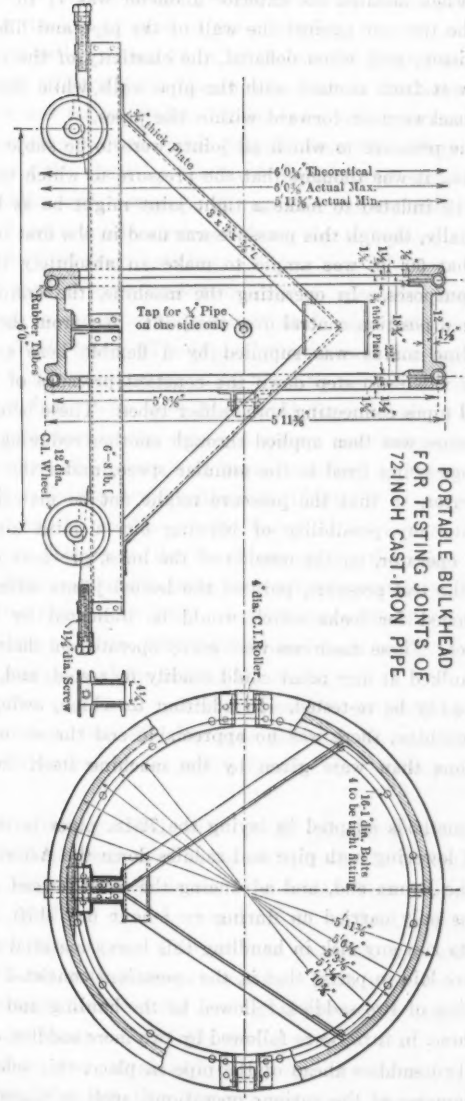
FIG. 21.

had two swinging arms, to each of which was attached a cable hoist, operated by an air-driven ram, to lift the crane girders for the purpose of moving them ahead, section by section, as pipe-laying proceeded.

Although the laying of the mains in the tunnel was to be done by the tunnel construction organization, the jointing of the pipes, when and as laid, was to be done by the Street Department of Mains of the Company. At the same time, it devolved on the tunnel organization to subject all joints to test after they were caulked. The requirements were that each joint should be subjected to a test by air pressure at 20 lb. per sq. in., and that such test should be applied in each line of pipe as each ten pipe lengths were laid. It was obvious that this latter requirement would limit the progress of laying to the rapidity of caulking operations, and thus interfere seriously with procedure. Further, to consider plugging the end of the pipe main, and to have a portable end bulkhead to be erected and secured as each ten lengths were laid, would have involved great delay, as the caulking operations would have to be completed up to the last length laid before such testing could proceed. The writer, therefore, designed a novel machine (Fig. 22) for testing joints. This was a complete traveling outfit, consisting of a double bulkhead on a wheeled frame, which could be pushed by hand through the inside of the pipe mains and enclose any joint within an annular space. The two bulkheads consisted of pneumatic tires inflated to make a tight joint between the testing machine and the inside wall of the pipe. Two testing machines were assembled at the tunnel works, one being used for each line of pipe. The machine consisted of a cast-iron piston, 71½ in. in diameter, or ½ in. less than the internal diameter of the pipes. Previous to laying, a great number of pipes had been calibrated, and the internal diameter was found to range from a minimum of 71⅝ in. to a maximum of 72¼ in. This piston was 24 in. long, with exterior flanges, giving an annular space between flanges of 12 in. The two flanges were designed of cove form, to give close support to a soft and elastic rubber tube, and the exterior rings, attached by bolts to the center casting, like a junk ring to a piston, enabled the rubber packing rings to be inserted and, when inflated, to give the necessary support. These flanged grooves were fitted with a solid continuous tire tube, made of the finest inner tube rubber, and fitted with a standard automobile tire valve, the tube being 2½ in. in external diameter with ⅜-in. rubber walls. These tubes were made up



PORTABLE BULKHEAD FOR TESTING JOINTS OF 72-INCH CAST-IRON PIPE

Fig. 22.

so that when deflated the exterior diameter was 71 in. The inflation forced the tire out against the wall of the pipe and filled the grooves of the piston, and, when deflated, the elasticity of the rubber entirely withdrew it from contact with the pipe walls, while the machine was pushed backward or forward within the pipes.

As the pressure to which all joints were to be subjected was 20 lb. per sq. in., it was thought that the pressure to which the tubes would need to be inflated to make a tight joint might be as high as 80 lb., but, actually, though this pressure was used in the first instance, it was found that 50 lb. was ample to make an absolutely tight joint for testing purposes. In operating the machine, the annular space was moved to a position central over the joint. Air from the high-pressure tunnel line mains was supplied by a flexible hose and, through a reducing valve—to step down the constant pressure of 50 lb.—to the manifold pipes connecting both rubber tubes. These being inflated, the test pressure was then applied through another reducing valve, a pressure gauge being fixed to the annular space, under the observation of the operator, so that the pressure might not be materially exceeded, to obviate any possibility of blowing out a joint already caulked. Another operator, on the outside of the hubs, previous to the application of the test pressure, painted the leaded joints with soap solution and watched for leaks which would be indicated by the formation of bubbles. These machines were easily operated on their roller frames, joints caulked at any point could readily be tested, and, if re-caulked, could readily be re-tested. In addition to which, owing to the form of the machine, there was no appreciable end thrust to require other precautions than were given by the machine itself to balance that thrust.

The methods adopted in laying the 72-in. pipes in the tunnel consisted of lowering both pipe and saddles down the Astoria Shaft, hauling to the Bronx end, and advancing the work toward Astoria. This work was only carried on during an 8-hour day shift, as it was not desired to run any risk in handling this heavy material at night. The pipes were laid in pairs; that is, the operations consisted of the hauling and setting of two saddles, followed by the hauling and setting of two pipes; these, in turn, were followed by two more saddles, etc. By maintaining two saddles ahead of the pipe in place, this scheme permitted an overlapping of the various operations, such as placing and setting

saddles, setting pipe, moving crane girders, removing hauling track, etc., thus reducing the loss of time to the minimum.

The pipes, which varied within 1½ in. of the correct length, were all numbered, and were selected from the storage rows as the work proceeded. Each pipe was transported to the shaft by rolling it on skids by a single cable engine with the cable looped around it. They were lowered singly down the shaft by the steel derrick, and with every other pipe two saddles were lowered. A tag line was attached from the pipe to a steel cable guide stretched from top to bottom of the shaft, to prevent the load from twisting.

The pipes and saddles were landed directly on specially designed flatcars, and haulage to and from the point of work was by the endless cable system on a single track. The pipe cars were run at a speed of 6 miles per hour and the other loads at 10 miles per hour. These speeds were greater than those usually adopted for an endless cable system in tunnel work, but in this case the system was designed with the minimum number of sheaves and turns possible, so that these speeds were readily maintained and without accident.

On the arrival of the saddles at the point of work they were transferred from the flatcars to the tunnel invert by the crane and accurately set to alignment, grade being maintained by steel wedging beneath them. The pipes were taken directly from the flatcars to position by the crane, two 1-in. wire cable slings, each attached to a 10-ton chain block, being used for raising the loads.

The setting of the pipes was followed, some 200 ft. back, by the caulking, and this at a like distance was followed by the testing machines; so that there was no confusion between the various gangs engaged.

The joints were hand-caulked with small air-driven caulking hammers, hemp yarn and lead wool being well driven to a depth of 5½ in. into the caulking space, which was ⅝ in. wide. This required 4 lb. of soaped yarn, 10 lb. of dry yarn, and 225 lb. of lead, per joint, the latter including 2% waste. The average progress was sixteen joints caulked each day with sixteen hammers. Each pipe line was provided with a portable bulkhead for testing, as previously described. After this testing, the joints were thickly coated with red lead.

Excellent progress was attained in laying the tunnel pipe, especially considering the fact that the entire tunnel transportation

in both directions was over a single track. An average daily progress of twelve pipe lengths was attained for the whole work, and in the half tunnel length last executed the average progress was as great as sixteen lengths per day.

The erection of the structural steel runway proceeded from the Bronx end toward the Astoria Shaft, the material being lowered down the Bronx Shaft. No difficulty was found in doing this work at the same rate as pipe-laying, and it was not featured by any incident of unusual interest.

Personnel.—The undertaking herein described was carried out for the Astoria Light, Heat and Power Company (an organization closely affiliated with the Consolidated Gas Company of New York), and was under the general supervision and direction of Mr. William H. Bradley, Chief Engineer, and William Cullen Morris, M. Am. Soc. C. E., Engineer of Construction. Mr. Colin C. Simpson, Superintendent of Mains, had direct charge of jointing the pipes inside the tunnel and of laying the street mains connecting therewith.

The development of the plan for the project of building the Astoria Gas Plant and the Astoria Tunnel herein described, must be attributed directly to Mr. Bradley.

The design, engineering, and construction of this entire work were executed by Jacobs and Davies, Incorporated, as Tunnel Engineers, for whom the writer acted as Engineer-in-Charge. The field engineering, including surveying, alignment, and detailed field work in connection with construction, was first in charge of Mr. G. F. Weismann, and during the later period was in charge of Mr. J. Chadwick Scott, who had previously acted as Assistant Field Engineer. The construction of the work, throughout, was in charge of Mr. Vivian Messiter as Engineers' Agent, assisted by Mr. Alexander W. Hodgson as Mechanical Engineer.

DISCUSSION

F. LAVIS,* M. AM. SOC. C. E. (by letter).—During the past few years there has been a notable development, and almost entirely in the vicinity of New York City, in the construction of tunnels at such depths below water level as to preclude the possibility of using air pressure to prevent the inflow of water, should seams in the rock afford it an opportunity to reach the tunnel with the full head due to the depth below the water surface. Mr. Lavis.

The other tunnels of this nature which have been built, have been along the line of the Catskill Aqueduct, where the restrictions confining the location within certain definite limits were not so rigid as in the case of the Astoria Tunnel, and, therefore, it was possible to fix them with greater regard for the avoidance of probable bad geological conditions. In the case of the deep siphons of the Aqueduct, sufficient diamond drill borings were taken to enable competent geologists to predict fairly successfully the character of the rock, and the location was made in such a way that the tunnel would lie wholly within the zone in which it was expected to find sound rock, free from faults, or to cross the latter at or nearly at right angles. So far as the writer knows, these expectations were reasonably well fulfilled, and although grouting of water-bearing seams was resorted to, and very high pressures were used, there has not been recorded, thus far, any experience comparable to that encountered in the Astoria Tunnel, and so well and fully described in this paper. The latter is unique in describing methods of driving a tunnel through unstable ground with seams of decomposed rock having direct connection with navigable waters, at a depth of more than 100 ft. below the lowest depth at which work could be carried on under air pressure, the recovery of the tunnel after complete flooding, and the solid grouting of the whole tunnel section to form a stable material through which the tunnel was finally driven.

It seems to the writer that it is out of the question to discuss in much detail the methods described in the paper; we have had no similar experience with which to compare it—the situation was unique, the methods were effective, and the job is finished. Some other scheme might have been effective, but no one can say positively that it would, the only possibility known to the writer is freezing, and there is nothing in past experience to lead one to believe that it would have been better, or so good. Probably it is only effective in fairly homogeneous material softer than rock, and probably would not work at all in the shattered rock encountered in this tunnel.

The Society, as well as the author, is to be congratulated on the excellent manner in which the paper has been presented, and the

* New York City.

Mr. Lavis.

completeness of the description contained therein. The writer believes that his paper,* describing the construction of the Bergen Hill Tunnels of the Pennsylvania Railroad, contained the first tabulated statements in reference to any tunneling work in North America, showing number of feet drilled per cubic yard, quantities of explosives, actual drilling time, etc., though, in a lesser degree, such records had been published in regard to some of the Alpine tunnel work in Europe. He has noted, therefore, with considerable satisfaction, the presentation of similar data, not only in this paper, but in several other descriptions of tunneling operations in recent years. The statement of progress in number of cubic yards per shift or per day is far more definite than the statement of the number of feet of advance which may or may not be of the full clean section. The statement showing the complete items of the plant is most useful, as are also the details, so often omitted, of the smaller items, in regard to the excavation of the rock, such as quality of steel, sizes of holes, kind of fuse, batteries, etc.

The construction of the concrete arch to hold the roof in bad ground before building the side-walls or invert is not new in this tunnel, although it is a comparatively recent development in the art of soft-ground tunneling. So far as the writer knows, its first important use was in the Providence Tunnel of the New York, New Haven and Hartford Railroad, built about 10 years ago.

The question as to the desirability or otherwise of using dry rock packing to fill the space between the normal section of the lining and the actual excavation is an interesting one. In this case, as well as in nearly all cases of the tunnels on the Catskill Aqueduct, tight concrete packing and thorough grouting were clearly indicated as the only effective method of surely preventing the least disturbance by settlement of the surrounding ground. In cases similar to that of the Bergen Hill Tunnels of the Pennsylvania Railroad, however, the use of dry rock packing over the arch was not only far less expensive, but proved to be most effective in allowing the ground-water to reach the drainage pipes at the sides and thus enter the side drains in the floor, providing a dry tunnel with very little water-proofing.

The value of this paper and the importance of the work which it describes can only be fully understood by a realization of the fact that it marks a distinct step forward in the art of tunneling. For ages, almost, tunneling was only possible through fairly sound rock, or materials which could be held by close timbering. The shield and the use of compressed air, brought into really general use only within the last 30 years, although they had been used previous to that time, enable tunnels to be driven through water-bearing materials to depths of about 100 ft. below the surface of the water, the pressure at greater depths being so great as practically to prohibit effective work. We

* *Transactions*, Am. Soc. C. E., Vol. LXVIII, p. 84.

now have a method of driving tunnels at almost any depth in water-bearing ground, and, within certain limits, through almost any class of material. Mr. Lavis.

Perhaps it is not without interest at this time, when it has been suggested that mining engineers should be called in to advise as to methods of subway construction, to note—without in the least detracting from the ability of mining engineers and miners in their particular field—that nearly all the developments in the art of tunneling through difficult ground, beyond the art of timbering in comparatively small sections, have been made by civil engineers, and for transportation purposes, rather than by mining engineers or miners. In the really vast tunneling operations which have been carried on in New York City and its vicinity in recent years, it is undoubtedly within the bounds of truth to state that not only has this work been the greatest, most extensive, and most difficult of its kind, that is, of tunneling, ever undertaken and carried out successfully anywhere, but it has been done with fewer accidents, and all the engineers responsible for this state of affairs deserve commendation.

The record of this work on the Astoria Tunnel shows, also, as do all records of successful advances in the art of tunneling, and nearly all records in recent years of advance in the rate of progress, the absolute necessity of such preliminary study, careful planning, and efficient organization as usually only engineers are trained to carry out. It must be remembered, however, that though a carefully studied plan must be worked out and adhered to, engineers engaged in this kind of work must be able to adapt it to all sorts of variations as they arise. It is far from easy, amid the noise, dirt, partial darkness, and, oftentimes, apparent confusion underground, to carry out a plan which looks well on a drawing-board in a comfortable, well-lighted office; and when added to all this, the whole East River is likely to drop in on one at any minute, plans are likely to go by the board.

MILTON H. FREEMAN,* ASSOC. M. AM. SOC. C. E. (by letter).—One of the most interesting features of this paper is the description of the method of excavating through decomposed water-bearing rock. An excellent opportunity was afforded to obtain positive data concerning the results of the grouting, as the subsequent excavation exposed the grout-filled seams. In work of a similar character on the Catskill Aqueduct, the following were found to be essential features: Mr. Freeman.

1.—An impervious bulkhead against which to grout, which also furnishes an anchorage for the grout pipes;

2.—A grout tank pressure considerably above the rock water pressure against which grout is injected;

* Brooklyn, N. Y.

Mr. Freeman.

3.—Adapting the consistency of the grout to the size of the cavity to be filled, using thicker grout for very large seams, and very thin grout for the fine seams.

On the Catskill Aqueduct the first attempt to fill water-bearing seams ahead of the excavation was made at Shaft 4 of the Rondout Siphon. This difficult piece of work is fully described by John P. Hogan, Assoc. M. Am. Soc. C. E., in his paper entitled "Sinking a Wet Shaft".*

This shaft passes through water-bearing strata, 131 ft. thick. Nipples were swedged into drill holes, valves put on, and the drilling was continued through the pipe and valve into the softer water-bearing strata, the holes furnishing channels for grouting the rock seams. The method was quite similar to the procedure in the Astoria Tunnel. It was not found necessary to place a concrete blanket in the bottom of the shaft as a bulkhead against which to grout, though, at one time, the rock was so soft that considerable grout was wasted in clogging the surface seams. Altogether, 2 960 bags of cement were injected, and grout tank pressures up to 275 lb. per sq. in. were used, giving a net pressure over and above the ground-water of from 100 to 180 lb. per sq. in. Large seams were especially well filled, the largest one being 8 in. wide, and quantities of water, up to 400 gal. per min., were stopped at different groutings. As excavation progressed, however, there was considerable seepage from the smaller seams; this was not cut off, and, for the entire depth of the shaft, amounted to about 450 gal. per min.

At many other places along the line of the Aqueduct, the leakage from clean-cut open seams was stopped entirely. Near the east shaft of the Hudson River Siphon, an open seam discharging about 500 gal. per min. was completely dried by placing a concrete bulkhead across the heading and forcing in neat cement grout under a pressure of 700 lb. per sq. in., which was 200 lb. greater than the ground-water pressure.

It was common practice in permanent shafts, which were concrete-lined, to place this lining—at least, across water-bearing strata—during the process of shaft-sinking, putting in weep-pipes to vent the water, which pipes were grouted after the concrete had hardened. This method proved effectual in shutting off leaks of considerable size; for instance, a leak of 125 gal. per min. in Shaft 5 of the Rondout Siphon was completely shut off in this manner.

The grouting of the pressure tunnels proper involved one consideration which was not found in the case of the shafts, or in the case of any tunnel which, during use, is subject to normal air pressure. The lining in such a shaft or tunnel is in compression from the pressure

* *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 398.

Mr. Freeman.

of the surrounding rock, earth, or ground-water. The pressure tunnels of the Catskill System pass deep under the valleys, far below the hydraulic gradient, and will be operated under an outward pressure of from 150 to 650 lb. per sq. in.; although the ground-water pressure relieves much of this, there remain net bursting pressures up to 200 lb. per sq. in. under operation. Consequently, the total net outward pressure is great in the case of tunnels ranging from 11 to 14½ ft. in finished diameter. The concrete lining of such tunnels is not thick enough to hold under tension, and depends on the rock backing to carry the load. Seamy, water-carrying rock furnishes a ready channel to take away water which may escape through the concrete lining. Furthermore, rock which is very seamy and broken does not furnish such a good backing for the concrete lining. Thus, the grout which was injected into the surrounding rock seams, helped in two ways: in solidifying the rock and making a better backing for the concrete, and in closing some channels which would carry away any water that might leak through the concrete lining. To meet this condition, an attempt was made, by using the tunnel lining as a bulkhead, to grout farther back into the seams, and to fill smaller seams than had been done during the process of excavation.

The first trial was made at Shaft 4, north, of the Rondout Siphon, where the tunnel passes through the water-bearing High Falls shale and Binnewater sandstone, both of which are broken, porous rocks, particularly so at this point, as they are twisted and crushed in a fault zone. The length of tunnel in this rock is about 250 ft. During excavation an effort was made to grout off the leakage in the heading, and a little was stopped, but the attempt was not wholly successful. No concrete bulkhead was built against which to grout, and the rock was so weak that the face could not be solidified sufficiently to form a backing for grouting pressures. Finally, a test-hole was driven with a diamond drill 250 ft. ahead through the water-bearing strata. Gradually, the leakage decreased, indicating a lowering of the ground-water level, more pumps were put in, and excavation was completed without additional grouting. The maximum leakage in this section was 2 000 gal. per min. A complete account of this work has been given by B. H. Wait, Assoc. M. Am. Soc. C. E.*

The thickness of the concrete lining through this wet section was 24 in., twice the ordinary minimum thickness. As a drip-pan to protect the soft concrete from the incoming water, and as a form of reinforcement for the tunnel lining, a steel shell was erected for a length of 174 ft. This consisted of 6-in. I-beam ribs bent nearly to a circle, but open at one side, the open ends fitting to the concrete invert which was placed first. For a covering, $\frac{3}{16}$-in. plates were

* *Engineering Record*, Vol. LXIII, p. 660, June 17th, 1911.

Mr. Freeman.

bolted to the ribs, and no attempt was made to secure water-tight joints. The concrete invert contained a longitudinal drain with Y-branches to each side, which picked up the leakage. The tunnel at this point was on a 15% incline, and drained itself readily.

The space between the steel shell and the rock was very carefully dry-packed, and afterward the concrete lining was placed inside this shell. Two sets of grout pipes were used, one leading through the concrete to this dry-packed section, the other set being carried from 1 to 3 ft. into the rock seams.

The dry packing outside the concrete was grouted first, while the pipes to the seams remained open to discharge the rock leakage, except those which were closed temporarily on account of leaking grout, when some of the thick grout worked back into the larger seams. Before grouting the dry packing, the inward leakage was 900 gal. per min., but after this grouting was completed, the deep-seated pipes discharged only 540 gal. per min., as the thick grout had worked back into some of the larger seams and cut down the leakage.

A start was made to grout the rock seams proper by injecting an ordinary mixture (95 lb. of cement to 5½ gal. of water) of neat grout into a deep-seated pipe leaking about 4 gal. per min. and 3 bags of cement plugged the seam. Then, at the suggestion of T. H. Wiggin, M. Am. Soc. C. E., Designing Engineer of the Pressure Tunnels, this pipe was re-opened, cleaned out, and a very thin mixture used (23¾ lb. of cement to 28 gal. of water). Of the latter mixture, 24 bags were injected into this same hole which had refused at 3 bags of the thicker mixture. The use of the very thin grout was continued with grouting pressures up to 300 lb. per sq. in. The tunnel-service pressure was 100 lb. per sq. in., higher pressures being furnished by a Westinghouse (booster) compressor. Two compressors were piped with two grout tanks, so that either compressor could be used with either tank. With one tank charging and the other discharging, the stream of grout was kept practically continuous. The rock-water pressure grouted against was 20 lb. per sq. in. If a pipe took grout easily at a pressure of 100 lb., the mixture was thickened a little (47½ lb. of cement to 28 gal. of water), and, if this continued for some time, the thickening was increased to 1 bag per 28 gal. of water. When the injection pressure began to rise, the mixture was thinned again. Pipes were considered full which refused the thinnest grout under a pressure of 300 lb. It was noticeable that the grout traveled some distance (from 30 to 40 ft.) in the seamy rock, showing up at other pipes, and cutting down the leakage at those pipes and filling the seams back of them. Not more than one in ten of the pipes leading to the rock seams took any considerable quantity of grout, though every pipe was tried. After all grouting was completed in this section, the inward leakage was

Mr. Freeman.

less than 1 gal. per min., due, perhaps, to a good concrete lining and not wholly to grouting. In a length of 174 ft. of tunnel, 940 bags of cement were injected into the rock seams, the finished diameter of the tunnel at this place being 14½ ft.

After the ground-water level was restored, four test holes were drilled about 3 ft. out into the grouted rock, where heavy leakages had occurred at the time of excavation. Two of these holes were practically dry, the third discharged ½ gal. per min., but the fourth struck a water-bearing seam and discharged 71 gal. per min. The latter hole was in the bottom of the tunnel, the others were at the horizontal diameter and the top. It is conceivable that the bottom might show the poorest results, as the ultimate direction of grout flow is upward. A gauge reading showed the rock water pressure to be 117 lb. per sq. in.

Another section of the same siphon, through blocky, seamy Helderberg limestone, took 946 bags of thin grout in a length of 50 ft. Two test holes, 3 ft. into the rock, showed no leakage.

Though absolute assurance cannot be given that all the seams were filled, the volume of cement injected indicates that many of them were closed by this method, which thicker grout would have clogged at the openings and left unfilled.

A difficulty arose in grouting a combination of large and small seams, as the large seams furnished an easy egress for thin grout, and the small seams clogged at the entrance with the thicker mixture. By increasing the cement per batch, if the pressure of injection remained low, and decreasing it again as the pressure rose, an attempt was made to adjust the consistency of the batch to the size of the seam.

Mr. Bradley.

W. H. Bradley, Esq.*—At a time when the outlook on the tunnel work was very dark, a prominent official of the Company said to the speaker "I was informed by an engineer that the tunnel is a failure—that it will never be completed". The speaker replied "You have never heard me say that, when you do you may take it to be a fact; at present it is not a fact".

To carry Mr. Davies' description of the pipe testing a little farther: About 2 weeks ago, one of the main pipes in the tunnel was tested, first by filling it with water which was allowed to rise about 40 ft. in the stand-pipes, giving a pressure of about 20 lb.; the joints were then inspected thoroughly for possible leaks, after which the water was run out and an air pressure of 40 lb. per sq. in. was applied, each joint being inspected by applying soap and water. After this inspection, water was again put in, the stand-pipes being filled to the top of the shaft, which created a pressure of about 125 lb. per sq. in. in

* Chief Engineer, Consolidated Gas Company, New York City.

Mr. Bradley.

the pipe. This may seem to have been unnecessary—after the previous tests—but it was a precautionary measure intended to expel all air from the pipe, because air and gas form an explosive mixture and there is likely to be serious trouble if a light reaches it. When the pipe was filled with water, the gas valves at both ends were opened, and, as the water was drawn out, the main was filled with gas with no mixture of air. This main is now in daily use.

The same procedure is being followed with the second main.

The head-houses are now being erected over the tunnel shafts, the elevators, pumping plant, telephone and lighting circuits are being installed, and the work will soon be completed.

Mr. Sanborn.

JAMES F. SANBORN,* ASSOC. M. AM. SOC. C. E.—It would be interesting to have a description of the difficulties in putting in the vertical pipes in the shaft. Were any curving rings or shims required? The speaker asks for this information because, in the work of the New York Board of Water Supply, there was trouble in erecting the risers of the City tunnel shafts, which were steel pipes, and it was found expedient to use a hub and spigot arrangement.

Mr. Wegmann.

EDWARD WEGMANN,* M. AM. SOC. C. E.—This paper is a very valuable contribution to the engineering literature of tunneling, and, doubtless, will be consulted by other engineers who encounter difficulties similar to those met in the Astoria Tunnel. The paper is very complete, as it describes in detail, not only the construction of the tunnel, but, also, the plant and methods used.

The speaker is particularly interested in the paper because he was one of the engineers on the tunnel, constructed in 1885 to 1891 under the Harlem River as part of the New Croton Aqueduct, in driving which decomposed rock, similar to that described by the author, had been encountered. The tunnel was about 1 300 ft. long and required a circular excavation, 14 ft. in diameter.

Before the work was begun, numerous diamond-drill borings were made to ascertain the character of the rock through which the tunnel was to be driven. Near Manhattan Island the rock was found to be gneiss, but for the greater part it was limestone having many seams. A pocket of decomposed rock was discovered in the gneiss formation, and was investigated by making borings about 50 ft. apart.

Based on the indications of the diamond-drill borings, the tunnel was planned so as to have its invert about 155 ft. below mean tide. It was thought that at this level there would be at least 30 ft. of solid rock above the tunnel, but when the heading had advanced about 300 ft. from Manhattan Island, a seam of rock, full of water, was struck by the drills. Water poured into the tunnel, and the workmen ran

* New York City.

for their lives. Sand and stone soon filled the drill holes, and made it possible to close them with wooden plugs. Mr. Wegmann.

A diamond drill was taken into the heading, and the ground in front and below the heading was explored by borings. In order to insure safety while this work was going on, a strong timber bulkhead, with a suitable gate, was built in the heading, just back of the diamond drill.

The test borings showed that the seam of decomposed rock extended about 75 ft. below the tunnel, instead of terminating 30 ft. above it, as had been believed by the engineer. In front of the heading, the seam was found to be 28 ft. wide, and beyond it there was limestone containing seams in which the water was under the full pressure due to the river, *i. e.*, under a head of more than 150 ft.

The important question arose as to how the tunnel was to be constructed through the seam of decomposed rock and through the limestone. Negotiations were held with the company controlling the patents for the freezing process, which had been used very successfully for sinking shafts through quicksand. This company was very willing to undertake the work on a percentage basis, but would not give any guaranties with regard to success.

The engineers in charge of the work were anxious to try to drive a pilot tunnel through the soft ground, but the contractor who was to do this work was very loath to undertake it, as it necessitated buying large pumps. Apparently, he had more influence with the Aqueduct Commissioners, under whose direction the New Croton Aqueduct was built, than the engineers of the Commission. By an order of this Commission, the engineers were directed to abandon the 300 ft. of tunnel that had been excavated to the soft seam, and to start another heading about 307 ft. below mean tide. At this level no difficulties were encountered.

The only additional cost of constructing the tunnel at the new level was in the lowering and hoisting of materials, but this was more than offset by the fact that the tunnel was very dry at the lower level. In spite of these circumstances, the contractor, assisted by able counsel, sued the City of New York for seventy items, aggregating about $350 000, for the additional cost of constructing the tunnel at the lower level, and for some other extras. The original contract price for the work was only about $500 000.

The lawsuit against the City was begun in 1890, but the contractor's lawyers waited 16 years, before they brought the case to trial. They thought, probably, that their chances of success would be better when the engineers and inspectors, who had been connected with the work, had gone West or died. The City won the suit twice, but the Court of Appeals sent it back a third time for re-trial. The case was about finished before a referee, when this gentleman, un-

Mr. Wegmann. fortunately, died. Twenty-four years after the suit was begun, it was settled out of Court by the City paying the contractor $25 000 on claims amounting to $350 000. It would be interesting to know what part of the $25 000 was received by the contractor's lawyers and how much by the contractor himself. The speaker mentions this lawsuit to show some of the difficulties, other than soft seams, which engineers encounter in tunneling.

Mr. Kellogg. R. C. KELLOGG,* ASSOC. M. AM. SOC. C. E.—The Astoria Tunnel is one of the principal connecting links in a vast scheme of gas distribution which comprehends sending out from the Astoria works, at some future time, approximately 200 000 000 cu. ft. of gas every 24 hours, part of which may eventually be pumped as far as Albany. This will not only rid Manhattan Island of unsightly gas manufacturing structures, but will also benefit the towns through which the supply may travel. The Astoria gas plant itself, when completed according to the plans conceived, will contain ten units, each capable of manufacturing 20 000 000 cu. ft. of gas every 24 hours, and ten storage holders each having a capacity of 15 000 000 cu. ft.

Mr. Brush. W. W. BRUSH,† M. AM. SOC. C. E.—It may be of interest to mention the fact that the engineers of the New York Board of Water Supply studied a line for a water supply tunnel which would follow somewhat closely that of the gas tunnel the construction of which has been described so clearly and interestingly by Mr. Davies. The future water supply of New York City will necessitate the delivery of large quantities into Queens Borough, which contains the maximum area available for development within the city, and where eventually an enormous manufacturing center will probably be found, with a large consumption of water.

The studies made several years ago to locate the tunnel to deliver the Catskill supply to the five boroughs indicated that a rock tunnel could probably be driven successfully into Astoria and carried through the rock into the Borough of Brooklyn, but that the cost would be decidedly greater than a tunnel along the adopted line under the Bronx and Manhattan to Brooklyn. One of the uncertain elements of cost was the driving of the tunnel under the East River, probably passing under Randall's and Ward's Islands. The question of determining the character of the rock at the contacts between the various formations was deemed to be a difficult problem.

Ultimately, however, in all probability, a tunnel will be driven under the East River, near the Gas Company's tunnel, for the purpose of delivering an additional water supply to the Borough of Queens and in part to the Borough of Brooklyn. The experience of the Gas

* Brooklyn, N. Y.
† New York City.

Company will then furnish especially interesting and valuable information for the engineers who will lay out the line and grade of the later tunnel. A water tunnel can readily be driven at any depth desired, and therefore the engineers may avoid some of the difficulties mentioned by Mr. Davies. Mr. Brush.

The riser pipes in the shafts of the Astoria-Bronx tunnel are embedded in concrete, and are therefore self-supporting.

THOMAS H. WIGGIN,* M. AM. SOC. C. E.—In the Catskill Aqueduct pressure tunnel siphon the rock conditions were similar to those described by the author. The first case was in the sinking of Shaft 4 of the Rondout inverted siphon which crosses the valley of Rondout Creek near High Falls, west of Kingston, N. Y. This was described in a paper† by J. P. Hogan, Jun. Am. Soc. C. E., and a discussion by the speaker adds other data, notably some from a very interesting shaft of the Detroit Salt Company. In Shaft 4 of the Rondout Siphon heavily water-bearing rock was encountered, as had been predicted from the preliminary borings and pumping tests in certain of these borings. At a depth of about 225 ft. the inward flow was more than 800 gal. per min. At first ordinary drill holes, and finally diamond-drill borings, made around the periphery of the shaft from the level to which sinking had progressed, were grouted, after which excavation was resumed with continued precautions as to drilling, carrying a pilot hole ahead and grouting through water-bearing drill holes. The leakage was very much reduced by the grouting, and would doubtless otherwise have reached very large quantities. In grouting this shaft, 971 bbl. of cement were used. Some of the seams were wide, 8 in. being the maximum. Mr. Wiggin.

The grout when encountered in the seams during subsequent excavation was like moderately soft limestone, and showed very fair strength.

Later, in the tunnel driven from this shaft, the same wet rock strata were encountered, again in the position expected from the borings, and similar grouting was done in advance of excavation, though not so successfully. The maximum leakage into the tunnel in this stretch was about 2 000 gal. per min. This did not interfere so much with operations as it might have under other conditions, because the tunnel was driven up on a 15% grade. The water made a very pretty cascade. A heavy concrete bulkhead, with a door, had been built between this stretch of tunnel and the shaft, in order to avoid loss of the tunnel in case of meeting a sudden inflow.

Much of the rock in this piece of tunnel was divided into very small blocks by water-bearing seams, and the impression was gained,

* New York City.

† *Transactions*, Vol. LXXIII, 1911, p. 398.

Mr. Wiggin. from such grouting as was done, that general impregnation by grout would be impossible with any practicable number of holes. Hence, the leakage was taken care of by a system of bottom drains and a shield of steel angle ribs and plates laid shingle-wise, which kept the water off the concrete while it was being placed. The space behind the steel was at first "dry-packed" with rock fragments, and was grouted after the concrete lining had been placed within the shield. The drains were also grouted. This method resulted in making this very wet portion of the siphon almost bone dry when completed.

In the Hudson Tunnel, where grouting pressures of about 1 000 lb. per sq. in. were used, the rock is generally solid and hard. It is what most people, from casual examination, would call a granite; geologists call it granodiorite. In general, the rock was rather tight, but within 2 or 3 ft. of a drill hole that was almost dry, another hole struck a flow of about 200 gal. per min. which temporarily overcame the pumping facilities causing the heading, which was then about 275 ft. long, to fill.

After the tunnel was pumped out, the leakage was collected in pipes, and a concrete bulkhead was placed at the end of the heading and anchored to the rock by steel rods. Four or five additional drill holes were made into the water-bearing region, which was identified by feelers as a narrow seam across the tunnel. The combined flow of all holes previous to grouting was found to be about 550 gal. per min., but was under control by gated pipes. A ground-water pressure of 400 lb. per sq. in. was recorded when the pipes were closed. The seam was finally grouted through the drill holes under a pressure of 1 000 lb. per sq. in. The tunnel at that point is more than 1 100 ft. below sea-level, and this high grouting pressure was required to overcome the ground-water head and the friction of the grout.

The equipment generally used on the Catskill works for grouting is a tank with top door and various pipes arranged so that the grout may be mixed by the release of air through the bottom pipe and ejected by forcing air into the top of the tank. This is the so-called Canniff grouting machine. In the Hudson Tunnel, air at a pressure of 1 000 lb. was not available for forcing out the grout. At first the attempt was made to pump the grout by plunger pump, but the pump valves soon wore out. The pump was then repaired and used to force water instead of air into the grouting machine on top of the grout, thus causing gradual dilution as well as displacement of the grout, but doing perfect grouting nevertheless.

A heavy concrete bulkhead, with a thick hinged cast-steel door, had been placed across the tunnel to prevent another flooding, and a liberal pumping equipment was put in. The tunnel was then driven through the wet ground, and a narrow seam which had been grouted could be

seen across the roof and sides of the tunnel, with only a few drops of water coming from it here and there. Mr. Wiggin.

This Hudson Tunnel, which is about 3 020 ft. long, had been explored by about a dozen vertical holes and by two pairs of inclined borings, the longest of which was about 2 052 ft. The holes of each pair of inclined borings passed each other near the middle of the river and solid core was taken from all the holes, so that it was known that the tunnel would be in good granite nowhere less than 150 ft. thick above the tunnel. Although considerable water in the aggregate was encountered in these holes, as is usual in granite, so large a flow concentrated at one seam was surprising, particularly as at that point the rock was not less than 700 ft. thick above the tunnel. This experience serves to emphasize the fact that in many kinds of rock very wet seams may be found, surprisingly close to very dry ground and under a thick roof of apparently sound rock.

The speaker has been very much interested in Mr. Davies' paper, and particularly in the success of the method of grouting a large number of holes, and grouting back into the body of the rock. This process has been demonstrated very beautifully by this tunnel, and also by the Catskill work, and is doubtless bound to be used more and more in difficult ground. At the same time, the speaker thinks that engineers who have had experience with wet ground will be inclined more and more to keep away from it, even at a considerable expense for exploration and the deepening of the tunnel.

On the Catskill work it was found that depth was no particular drawback. When the engineers started planning pressure tunnels, 200 ft. was thought to be pretty deep for such purposes. Some of these early studies look rather absurd in the light of the finished work. The idea of liberal depth gradually gained force; and if some of the work were to be done over again, even greater depths would probably be used in places.

WILLIAM CULLEN MORRIS,* M. AM. SOC. C. E. (by letter).—In relation to this paper, some information relative to the accident and casualty features of the work may be of interest. At the start of operations the Company decided, in view of the high rates prevailing for work of this class, to undertake the insurance, instead of placing it with a casualty company. A very liberal policy was adopted by the Company in the treatment of the men, allowing them full time during incapacity owing to any cause (either illness or accident) and furnishing medical attendance and supplies during the period of disability. Field hospitals were maintained at each end of the tunnel, with orderlies in constant attendance. Arrangements were made with neighboring hospitals for prompt ambulance service in case of emergency, and every Mr. Morris.

* New York City.

Mr. Morris. precaution was taken so that injuries could be treated to the best advantage. A physician was employed to supervise each of the hospitals, and the orderlies reported directly to these physicians all cases of first aid or disability treatment.

A force was organized for continuous inspection of the work, with a view of eradicating all preventable causes of accidents, the inspectors patrolling the work and immediately bringing to the attention of the tunnel force any features they might notice which might result in accidental injury. This feature of the work created some confusion for a time, but after several weeks of trying out, the arrangements were perfected to such an extent that there was no interference with rapid progress.

The accident treatment record and accident prevention were all under the direct supervision of the Company's Engineer, Mr. Harold Carpenter, who reported to the Company's construction office.

The record of accidents throughout the work is as follows:

Total accidents	1 525
Serious accidents	115
Total time lost	1.78%
Cases sent to outside hospitals	24
Cases treated in tunnel hospital	67
Cost of accidents in relation to pay-roll	5.36%

Mr. Davies. JOHN VIPOND DAVIES,* M. AM. SOC. C. E. (by letter).—The very interesting contributions by Messrs. Freeman, Wiggin, and Wegmann, as to the experience in the Catskill Aqueduct, illustrate the principal points of difference between that undertaking and the Astoria Tunnel. In the latter the primary feature was the consolidation of the soft and partly decomposed rock in order to permit of the construction of the tunnel, and, secondarily, the filling of the fissures, for the purpose of stopping leaks. The primary feature in the case of the Catskill Aqueduct was the absolute filling of all voids and the stoppage of leaks, and, secondarily, the consolidation of the rock.

For the stoppage of leaks and the consolidation of the rock, considerable grouting had been done in 1892 and 1893 in the construction of the East River Gas Company's tunnel at 70th Street, Manhattan, referred to in the paper. At that time the writer ordered cement, specially burned, with the elimination of any plaster admixture, so as to obtain the most rapid setting material. That tunnel was constructed at a comparatively shallow depth, and there was so little cover between it and the bed of the river that high pressure could not be used. The same condition occurred in the construction of the Hudson and Manhattan Tunnels, where large quantities of cement grout were also

* New York City.

used for the purposes just referred to, and, in that case, also, the comparatively shallow depth of these tunnels precluded any high-pressure grouting. In this latter case it was found that grout would follow the line of least resistance and pass out with little interruption into sewers, drains, or watercourses, without generally spreading into the soil, to give the results which were attained with the high pressures and greater resistances encountered in the Catskill Aqueduct and the Astoria Tunnel. Mr. Davies.

Mr. Sanborn inquires as to the erection of the vertical risers. These pipes were of cast iron, $2\frac{3}{4}$ in. thick, with hub and spigot joints. It was specified that they were to be machine-faced on the bearing surfaces in hubs and ends of spigots, so that there should be a true fit at every joint. Unfortunately, the facing of the two ends was not executed from common centers, the result being that these pipes—which as designed should have given perfect vertical alignment—were, when erected, found to be in error, with a regular creep from the vertical, due to imperfections in foundry work, and this necessitated the use of wrought-iron shims to bring them into correct vertical alignment.

Mr. Lavis refers to the relations of mining engineers to the various tunnel operations now being carried on in New York City. It occurs to the writer that there is a general misunderstanding as to the use of the term "mining engineer" in this respect. In common with other engineers engaged on subway construction in New York City, the writer has been, to a considerable extent, brought up with coal mining and other underground operations. The timbering and methods of construction used by coal and metalliferous miners are as far removed from the methods of the engineer engaged in subway work as it is possible to conceive. The class of mining involved in subway and tunnel construction is distinctly a development of business, entirely apart from the ordinary practice of those engineers engaged in such purely mining operations. The men employed in England are known as "miners", but this class consists of those essentially engaged on engineering work in heavy soft ground tunneling, not in mining operations. A large majority of those engaged in this business in New York have learned their trade in Europe, or from those who have brought the art from Europe, and there should be no conflict in the distinction between so-called mining engineering and engineering connected with tunnel work. The so-called mining engineer knows little of the type of timbering used in these tunnels.

Mr. Morris calls attention to the provisions for attending to accidents and casualties. The writer desires to state that in the treatment of employees injured or incapacitated on this work, the Astoria Light, Heat and Power Company provided more liberally than any

Mr. Davies.

employer with whom he has had any previous experience. As there were no hospitals in the vicinity of the shafts, the officers of this company decided to build them especially for this work; they equipped them completely, not only for rendering first aid, but also for the actual treatment of cases under competent medical supervision. The adjustments with employees were most liberal, and it is of interest to note that, notwithstanding this great care and the liberality in all cases, the entire cost of the accident account amounted to only 5.36% of the pay-rolls.

Paper No. 1360

CONCRETE-LINED OIL-STORAGE RESERVOIRS IN CALIFORNIA: CONSTRUCTION METHODS AND COST DATA*

By E. D. Cole, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. C. P. Bowie, Emile Low, Ralph J. Reed, and E. D. Cole.

Synopsis.

This paper describes briefly the construction of concrete-lined earthen reservoirs used for storing crude petroleum in the oil fields of California, giving in detail the methods used to obtain safe and economical results, together with the total cost of storage per barrel of capacity.

The method used in building up a compact and unyielding embankment as a backing for the concrete lining is given special attention.

The losses of oil, due to evaporation and seepage, are given for both lined and unlined reservoirs, showing the economy of the concrete lining.

Discussion is requested in particular on the question of expansion joints in work of this class, and also on the permeability of concrete subjected to the pressure of crude oil at low heads.

Quite a number of large earthen oil-storage reservoirs have been constructed in the numerous oil fields of California, and the

* Presented at the meeting of September 15th, 1915.

writer, being unable to find any literature covering this subject, and having been actively engaged for the past 3 years on construction of this class, thought that a brief description of the methods used and some unit costs would be of interest to engineers.

In general, these reservoirs are circular in plan, with earthen embankments built up from material excavated from within the reservoir, and range in capacity from 500 000 to 1 000 000 bbl. Some of the larger ones are oblong in plan, with circular ends connected by a rectangular section in the middle. In many cases dependence has been placed on the earth alone to prevent loss of oil by seepage, but it is now becoming general practice to line the inside slopes and bottom with a thin layer of reinforced concrete as an additional safeguard against leakage. The reservoirs are covered with a wooden roof supported usually by 6 by 6 or 8 by 8-in. posts resting on wooden footings or concrete piers. Two of the largest of these reservoirs were built entirely of reinforced concrete by the Union Oil Company at San Luis Obispo, Cal., in 1906, a partial failure of one of which has been noted in the technical press.*

It is the purpose of this paper to describe the construction of one of two 750 000-bbl. reinforced concrete-lined reservoirs, built by the writer, for the Kern Trading and Oil Company, at Bakersfield, Cal., during the winter and spring of 1913-14. The general dimensions of the reservoirs are as follows:

Inside diameter (bottom)	462 ft.
Inside diameter (top)	528 "
Depth	22 "
Width of top of embankment	11 "
Inside slope	1½ : 1
Outside slope	1½ : 1
Thickness of concrete lining (bottom)	3 in.
Thickness of concrete lining (top)	2½ "

Earthwork.—The formation at the site was a light sandy clay, and this was easily handled by the Fresno and wheel scrapers used throughout the work. After the site was cleared of all brush and grass, the foundation under the embankment was thoroughly plowed and wet down before the fill was started. Water for moistening the material

* *Engineering News*, March 16th, 1911, p. 310.

was supplied through a 2-in. pipe line laid around the site, just outside the outer line of slope stakes, with hose connections approximately 100 ft. apart. A 2-in. line was also run to the center of the reservoir to supply water to the portion of the site which could not be reached from the outside line. To avoid being in the way of the scraper teams, this pipe line was laid through one of the three 12-in. outlet pipes that were placed in position under the fill at the beginning of the work. A narrow trench was dug from the inner end of this outlet pipe to the center of the reservoir, and the 2-in. line was laid in it. This line was lowered from time to time as the work progressed, and was kept far enough below the surface of the excavation to be clear of the plow and scraper teams. Wetting down the excavation material was a help in several ways, as it not only made a more compact bank, but kept the dust down and made the earth ride better in the scrapers. This may seem inconsistent, inasmuch as the work was done during the rainy season, but can be readily understood on taking into consideration the fact that only 6 working days were lost during the winter on account of wet weather. The embankment was built up in thin layers, about 3 in. thick, laid parallel to the floor of the reservoir, and well compacted. In addition to the tramping of the scraper teams, the fill was compacted by two petrolithic road tampers which were driven continually around the top of the embankment.

To insure a compact and uniform backing for the concrete lining, on the inner slope below the natural ground surface, the excavation was started 2 ft. (measured normal to the slope) inside the inner line of slope stakes. This necessarily increased the quantity of excavation, and left the embankment short on the inner slope by this quantity. After the completion of the main portion of the embankment, a lining of selected material, 3 ft. thick (measured normal to the slope), was built up against the inner slope, from sub-grade (1 ft. below floor grade) to the top of the finished fill. This extra foot of material was put on to insure a compact surface at the grade line of the inner slope, but was afterward removed, as will be described later. The refill is an important part of the construction because it would cut off any layers of sand or loose material that might be encountered in that portion of the inner slope which lies below the ground surface. On some previous work it was found necessary to excavate and refill portions of the natural embankment, below the ground surface, after

the fill had been completed and trimmed to grade; this work caused considerable delay and added expense. One concrete-lined reservoir in this field partly failed, due to neglect of this part of the work, necessitating heavy expense in emptying the reservoir, besides the loss of a considerable quantity of oil and the cost of patching the lining.

Fig. 1 illustrates the method used on the first reservoir, in which a refill was put in. This particular section of the embankment was all in cut, in a loose gravel bank, making it imperative to put in a lining of sandy clay as a backing for the concrete. This refill or lining of selected material was started with Fresno scrapers, but these were soon abandoned in favor of wheel scrapers, on account of the difficulty in keeping them from sliding over the edge, and also because the wheel scrapers would build up a bench of the required width, and it was impossible to keep within the limits with the Fresnos. Apparently, the wheel scrapers build up a more compact lining, as will be noticed by referring to Fig. 2, which gives a close view of this particular piece of bank after it had been completed and trimmed off, and had been exposed to a heavy thunder shower. The lower portion of this view shows the upper edge of the refill which was put in with the Fresnos, and the upper portion shows the work done with wheel scrapers.

Trimming Slopes.—On the completion of the main embankment and the refill, the excess material on the inner slope, which ranged in thickness from 1 ft. at the top to 2 ft. at the bottom, was trimmed off leaving the slope smooth and true to grade. For this work of trimming the slope, a novel and (the writer believes) original method was used. Grade stakes were set on radial lines, both at the top and inner toe of the slope, approximately every 10 ft. around the circumference of the reservoir. Men with mattocks and slope-level boards then dug narrow trenches, 1 ft. wide and true to grade, from the top grade stake to the stake at the toe of the slope. Then 2 by 4-in. timbers, 38 ft. long, each faced with a narrow strip of strap iron, were placed in the bottom of each trench to act as guides for a trimming machine which was used to finish that portion of the slope between the hand-dug trenches. Before using the planer, however, all excess material above the top of the 2 by 4-in. timbers was scraped off the slope with a specially made Mormon or Buck scraper which was dragged up and down the slope, power being furnished by a double-drum hoisting

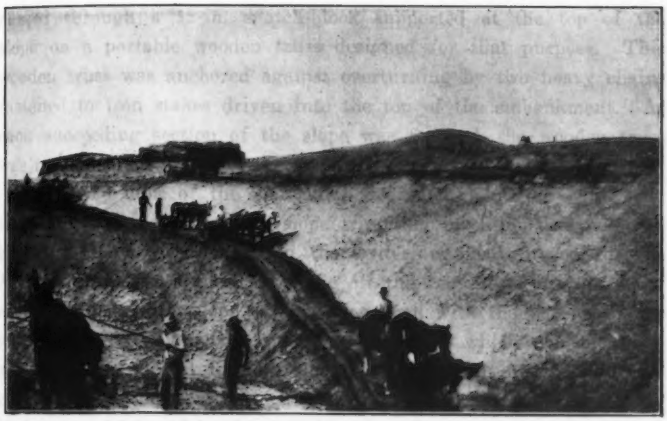

FIG. 1.—METHOD OF PUTTING IN REFILL OR LINING OF EMBANKMENT OF OIL-STORAGE RESERVOIR AS A BACKING FOR CONCRETE.

FIG. 2.—REFILL OR LINING OF EMBANKMENT OF OIL-STORAGE RESERVOIR COMPLETED AND TRIMMED OFF. UPPER PORTION PUT IN WITH WHEEL SCRAPERS, AND LOWER PORTION WITH FRESNOS.

engine at the center of the reservoir. The back-up line from the engine passed through a 12-in. snatch-block supported at the top of the slope on a portable wooden truss designed for that purpose. This wooden truss was anchored against overturning by two heavy chains fastened to iron stakes driven into the top of the embankment. As each succeeding section of the slope was finished, the wooden truss was moved along the top of the bank with a team of horses.

After the bulk of the material above the top of the 2 by 4-in. timbers had been removed, a slope trimming machine, designed and built by Mr. C. O. Zeller and the writer, was substituted for the Mormon scraper and used to plane off the remaining thin layer of earth and bring the slope to grade, or flush with the bottom of the guides. Fig. 3 shows the trimming machine, which consists of a rectangular frame, 11 ft. long and 6 ft. wide, built up of 6-in. steel channels bolted together and carrying two cutting blades. The cutting blades are of $\frac{3}{8}$ by 12-in. flat rolled steel, and are set at an angle with the frame of 1 to $2\frac{1}{2}$. The blades are also set at a slight angle longitudinally with each other, and the cutting edge projects down 2 in. below the bottom of the frame. The planer is dragged back and forth on the slope until the ends of the frame ride on the top of the guides, and that particular section is shaved off flush with the bottom of the guides, or down to grade. In this way nearly nine-tenths of the slope were finished by machine and at one-half the cost of doing the work by hand. One might naturally suppose that there would be considerable difficulty in keeping the guides in place without staking them down, but very little trouble was experienced. Loose earth would fill in the trenches around the guides as the machine worked above them, and this served to hold them in place. The trenches being dug on radial lines necessarily made them closer together at the bottom of the slope than at the top, but the blades of the planer were long enough to catch all the earth between trenches at the top of the slope and still have room at the bottom without binding between the guides. Fig. 4 shows the Mormon scraper working on a $1\frac{1}{2}$ to 1 slope in light sandy soil, and Fig. 5 on a 1 to 1 slope in a very heavy clay soil. An idea of the compactness of the face of the embankment can be obtained by a close inspection of Fig. 5, in which are to be seen the marks left by the teeth which it was found necessary to put on the blade of the Mormon to make it dig into the embankment. Fig. 6 shows

the planer working on a 1½ to 1 slope, and Fig. 7 on a 1 to 1 slope. The crew on all the trimming work consisted of only seven men, including the engineer who ran the hoist.

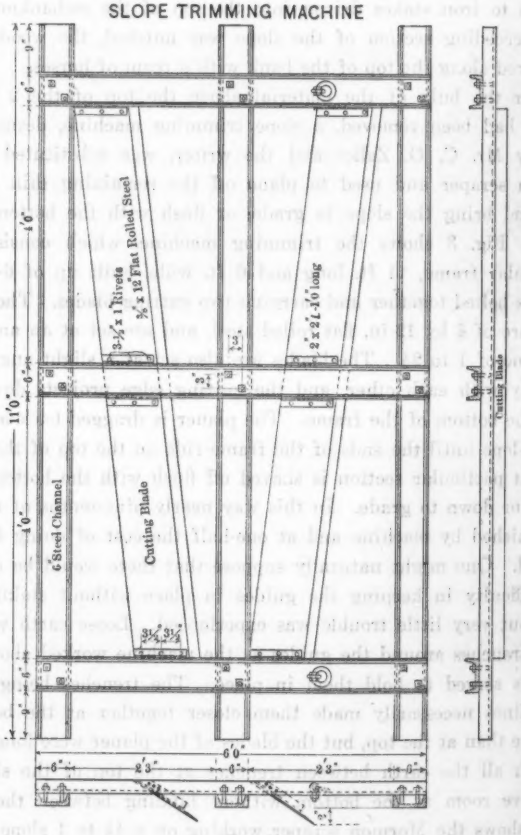

FIG. 3.

Floor.—The floor of the reservoir was excavated to a depth of 1 ft. below grade, and the sub-grade was plowed and well rolled before commencing the refill upon it. It was then back-filled to grade, built up in thin layers, moistened, and well rolled with petrolithic road tampers.

FIG. 4.—MORMON SCRAPER WORKING ON A 1½:1 SLOPE IN LIGHT SANDY SOIL.

FIG. 5.—MORMON SCRAPER WORKING ON A 1:1 SLOPE IN HEAVY CLAY SOIL.

FIG. 6.—SLOPE TRIMMING MACHINE WORKING ON A $1\frac{1}{2}$:1 SLOPE.

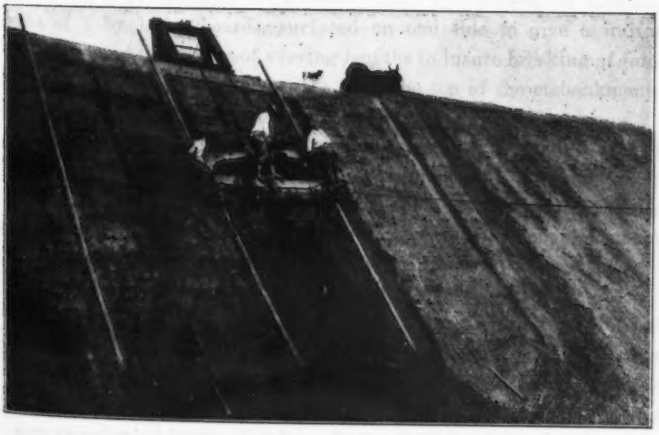

FIG. 7.—SLOPE TRIMMING MACHINE WORKING ON A 1:1 SLOPE.

Sand and gravel patches in the floor below sub-grade were excavated to a depth of 3 ft. below floor grade and then refilled with selected material. The floor was rolled smooth and hard to grade with a 5-ton road roller, a variation of only 0.05 ft. from true grade being allowed.

Pier Footings.—Excavations for the pier footings were made and the concrete piers for the roof supports were poured. Before pouring the concrete piers, however, and after the footings were dug, the floor reinforcing metal, which consisted of one layer of Clinton electrically welded fabric, made up of No. 6 wire in 6-in. square mesh, was laid out over the floor and tied together. The piers were poured through this metal, and later, when the floor was poured, this method left the reinforcing metal continuous throughout the floor and piers, without any patchwork.

Roof.—The roof was supported on 6 by 6-in. posts, approximately 18 ft. apart on centers, resting on concrete piers, and placed in concentric rings around the floor of the reservoir. The rafters were of 2 by 8-in. lumber, 20 ft. long, and were supported by 3 by 12-in. girders, 18 ft. long, which were notched into the tops of the posts. The rafters were laid on radial lines toward the center post, and 2 ft. from center to center at their inner ends. The roofing, or sheathing, was of 1 by 12-in. boards, surfaced on one side to give a uniform thickness, and these were of varying lengths to insure breaking of joints. The rafters that bridged the space from the top of the embankment to the first row of posts at the toe of the slope (see Fig. 12), were of 2 by 14-in. lumber, 38 ft. long, and rested at their outer ends on 2 by 12-in. redwood mudsills on the top of the embankment. All posts and girders were cut to length before commencing the construction of the roof. Later, this lumber was hauled to the top of the embankment and skidded down to the bottom of the reservoir where it was loaded on hand-trucks and distributed.

Bents, consisting of two posts and a girder, were framed in the bottom and hoisted into position with a small hand derrick operating on the roof. This derrick consisted of a boom made up of two pieces of 2 by 8-in. lumber, 38 ft. long, supported in the middle on an ordinary two-wheeled lumber truck, and rigged with a 2-ton hand-operated hoisting crab. The hoisting line ran over a small sheave at the outer end of the boom, and consisted of $\frac{3}{4}$-in. pliable steel cable. While raising a bent, the outer end of the boom was anchored to a rafter

with a U-shaped bolt which could be quickly attached. Later, this system was changed somewhat, as the strain on the girder under the wheels of the derrick was considered too great for safety. The hoisting winch was transferred to the extreme end of the boom, which placed the men operating it over the second row of posts back from the edge of the roof, and only one post and a girder were raised at a time (Fig. 8). This method worked very well, and good time was made. The best day's work consisted in raising 145 bents in 9 hours, or about one-fifth of the total number in the reservoir. In fact, good time was made throughout the job, as the roof, consisting of about 600 000 ft., b. m., was erected in 7 days, with an average of 50 men.

In hoisting the bents, the derrick worked on only one row at a time, starting at the outer row and working toward the center of the reservoir. The hoisting crew was followed by a crew which placed the rafters, and this one was followed by a crew laying the sheathing. Joints in the sheathing were made on top of the rafters, and, on account of the large quantity of sawing necessary, a special rig was devised for this purpose. A 2-h.p. electric motor, belt-connected to a circular saw, Fig. 9, was mounted on a small hand-truck which could be wheeled around on the roof, and used to cut off the ends of the sheathing. Pencil marks were made where boards were to be sawed, and this work was done by 3 men, including the saw filer. Power was supplied by a near-by power line, the transformers being mounted on a pole just outside the embankment. Wires were run to the center post, and lead lines from there to the saw could be dragged to any part of the roof.

Concrete Lining.—The floor and slopes of the reservoir were covered with a lining of concrete reinforced with a continuous layer of Clinton electrically welded fabric, made up of No. 6 wire in 6-in. square mesh. The thickness of the floor lining was 3 in., and that of the slope 2½ in. The concrete was mixed in a Ransome batch mixer, of 1 cu. yd. capacity, placed at the outside toe of the slope, and was delivered into a hopper at the toe of the slope inside the reservoir by a hoisting tower and a 1-cu. yd. automatic dump bucket. From the hopper it was delivered into concrete buggies and wheeled to the spreading gang. In pouring the floor, a 1½-in. layer of concrete was first spread over a small section, and the reinforcing metal was then raised up through the concrete before the second layer was poured. After

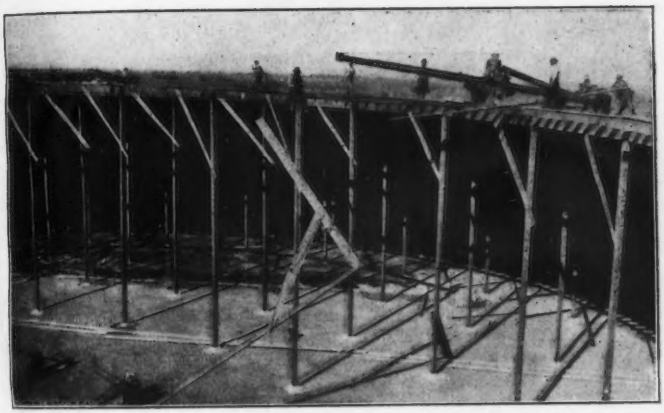

FIG. 8.—METHOD OF HOISTING BENTS INTO POSITION.

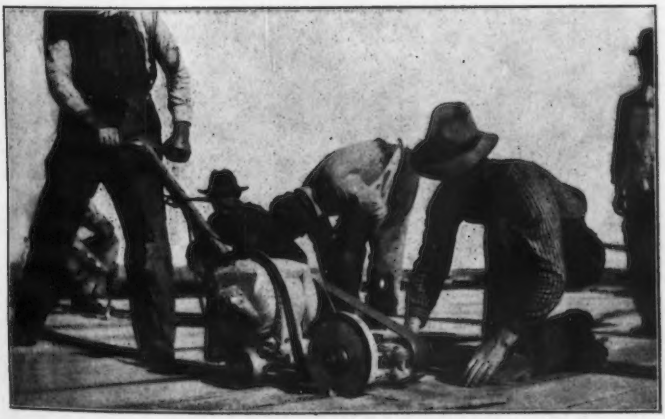

FIG. 9.—ELECTRIC MOTOR CONNECTED TO CIRCULAR SAW, USED TO CUT OFF ENDS OF SHEATHING ON ROOF OF OIL-STORAGE RESERVOIR.

pouring the slab, the concrete was tamped with wide-faced wooden tampers, and troweled smooth and even. The construction joint at the end of a day's work was beveled off, and, before placing concrete against it, on the following day, was swept clean of loose material and thoroughly grouted with a mortar of neat cement.

The concrete for the slope was delivered from the hoisting tower into small hoppers set on wagons and hauled with teams around the top of the embankment. From the wagons it was poured directly on the slope; no forms of any kind were used, as the concrete was mixed so that it would not run any more than enough to facilitate spreading. The slope lining was also put on in two layers, in order to insure that the reinforcing metal would be placed in the middle of the slab. No trouble was experienced in pouring the slope without the use of forms, as the concrete was mixed fairly "stiff", and was prevented from "sluffing" by the reinforcing metal. In fact, the writer has just finished lining a reservoir with side slopes of 1 to 1, for the Union Oil Company, at San Luis Obispo, Cal., without the use of forms and with no appreciable difficulty. Each day's work was gone over on the day following and swept with a cement wash mixed in the proportion of 1 of part cement to 1½ parts of water. This wash of grout was applied to fill up any small checks which might appear while the concrete was taking its final set.

No expansion joints, either in the floor or slope, were put in, on account of the comparatively heavy reinforcement of the slab and the low range in temperature to which the concrete would be subjected. Fig. 10 is a plan of the reservoir, and also shows some details of the reinforcement.

The concrete for the floor lining was mixed in the following proportions, based on a mechanical analysis of the aggregates, and combining the curves, as explained by William B. Fuller and Sanford E. Thompson, Members, Am. Soc. C. E.*:

1 part cement,
3 parts sand,
1½ parts of ½-in. crushed rock,
2½ parts of 1-in. crushed rock.

This mixture worked well on the floor, but was found too rocky for the slope, as it was very difficult to tamp the concrete and prevent it

from sluffing to the bottom of the slope. For this reason the 1-in. rock was eliminated, and the following mixture used:

1 part cement,
2 parts sand,
2 parts ½-in. crushed rock.

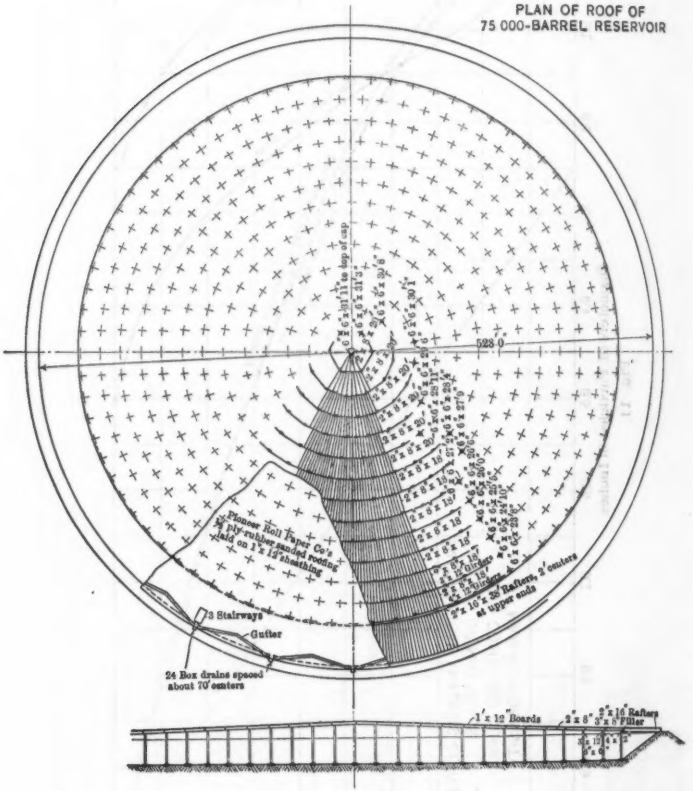

FIG. 12.

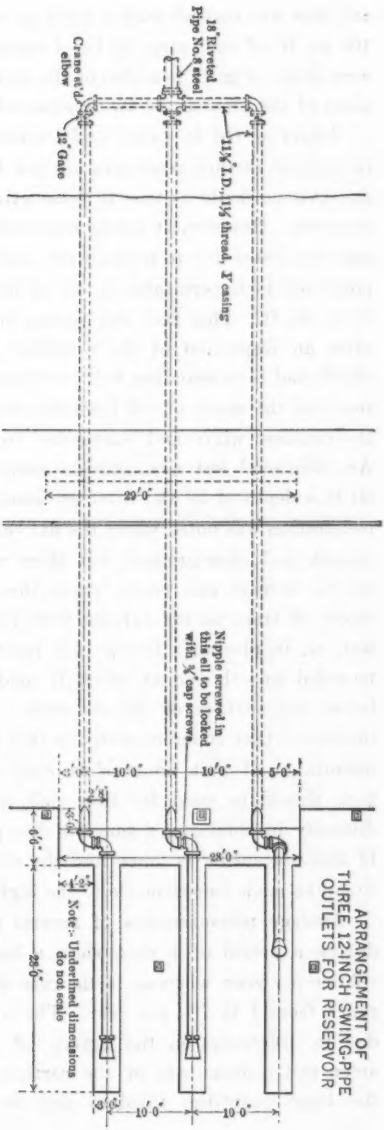
Fig. 11 shows the mechanical analysis curves.

The concrete crew, consisting of a foreman and 30 men, poured an average of 20 000 sq. ft. of lining per 9-hour day.

Roofing.—After the completion of the concrete lining, the roof was covered with a layer of Pioneer Paper Company's 1-ply roofing,



ARRANGEMENT OF THREE 12-INCH SWING-PIPE OUTLETS FOR RESERVOIR

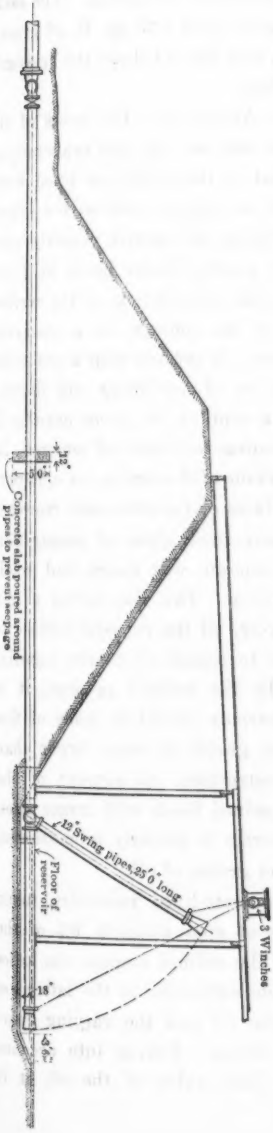


FIG. 13.

and this was covered with a layer of asphaltum and gravel. For each 100 sq. ft. of roof area, 30 lb. of asphaltum and 1.35 cu. ft. of gravel were used. Fig. 12 is a plan of the roof, and Fig. 13 shows the arrangement of the three 12-in. swing-pipe outlets.

Losses of Oil in Lined and Unlined Reservoirs.—The losses of oil in unlined earthen reservoirs are due to both seepage and evaporation, and this no doubt is true to some extent in those that are lined with concrete. However, it seems reasonable to suppose that in the latter case the losses due to seepage are negligible, as concrete properly proportioned is impermeable to oil of low gravity under heads of from 18 to 24 ft. This fact was proven to the satisfaction of the writer after an inspection of the condition of the concrete in a reservoir which had been standing full for 2 years. A scratch with a penknife removed the scum of oil from the surface of the lining and showed the concrete white and unattacked in a number of places examined. An additional test was made by suspending test slabs of concrete in oil to a depth of 20 ft.; after an immersion of 6 months, no apparent penetration was noted where the flat surfaces of the slabs were troweled smooth and close-grained, but there were some signs of penetration on the corners and edges where the concrete was rough and small pieces of stone at the surface were exposed. This was hardly a fair test, as, in placing a lining in a reservoir, all the exposed surface is troweled smooth and an effort is made to embed all coarse material below the surface of the concrete. In the writer's opinion, it is important that concrete used for this purpose should be made of fine material, and that no crushed rock or gravel in sizes larger than ¾-in. should be used for thin slab construction, on account of the difficulty in obtaining a smooth, close-grained finish with larger sizes. If this precaution is taken and the concrete is properly proportioned, it can be made impermeable to the higher grades of oil.

Average measurements of several concrete-lined reservoirs, taken during a period of 1 year, show a loss of approximately 1% of the volume per year, whereas, in the case of the unlined storage, the losses range from 1 to 7% per year. The wide variations in the latter are due to differences in the gravity of the oil and the varying character and compactness of the earthen lining. Taking into account the large quantities involved and the high value of the oil, it is

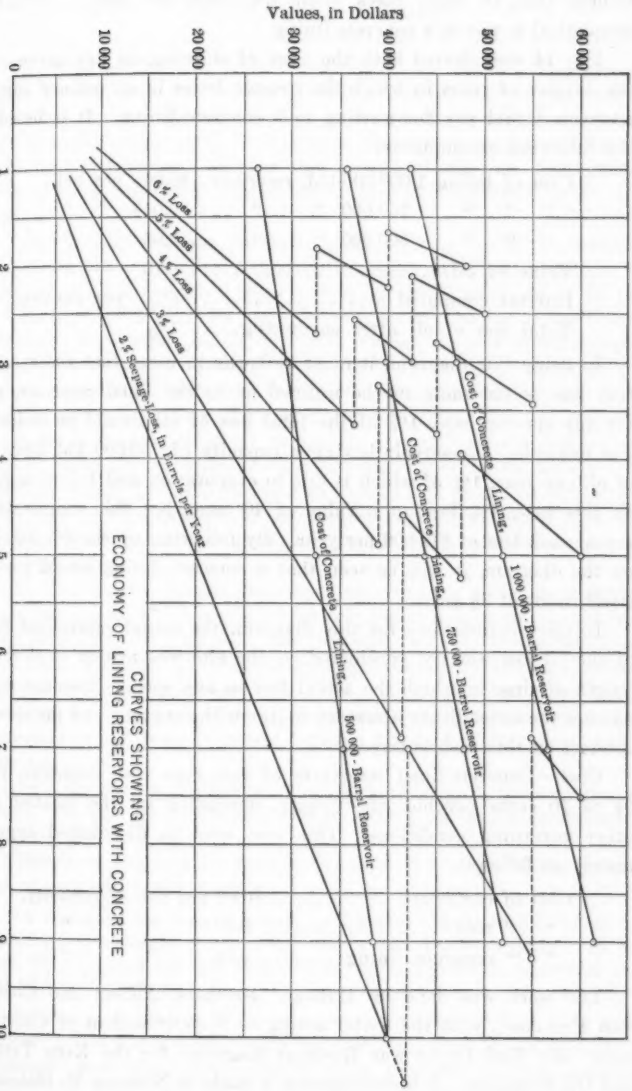

FIG. 14.—CURVES SHOWING ECONOMY OF LINING RESERVOIRS WITH CONCRETE

evident that, in many cases where the losses are large, it would be economical to put in a concrete lining.

Fig. 14 was plotted with the view of showing, in any given case, the number of years in which the seepage losses in an unlined earthen reservoir would pay for putting in a concrete lining. It is based on the following assumptions:

Cost of lining	1 000 000-bbl. reservoir	$0.04	per bbl.
" " "	750 000 " "	0.04½	" "
" " "	500 000 " "	0.05	" "
Value of oil		0.40	" "
Interest computed at		6%	per annum.
Total loss of oil after concreting		1%	" "

In using this diagram, it must be borne in mind that the evaporation loss is the same in the unlined as in the lined reservoir, and, for any specific case, 1% of the total loss of oil should be deducted. For example: A reservoir having a capacity of 750 000 bbl. loses 5% of oil per year, 1% of which is due to evaporation and 4% to seepage. In this case, 4% loss, at a value of 40 cents per bbl., represents an actual cash loss of $12 000 per year. By following up the 4% loss line on the diagram, it will be seen that a concrete lining would pay for itself in about 3½ years.

In the computations for this diagram, the actual capitalized value of the oil loss was not considered, as the aim was merely to show the length of time in which the actual loss in any specific instance would balance the expenditure necessary to line with concrete, and the accrued interest on this cash outlay.

Cost.—Concrete-lined reservoirs of this type cost, complete, from 9½ to 10 cents per bbl. of capacity, depending on the location and other governing conditions. This cost may be distributed approximately as follows:

Cost of earthwork	$0.03	per bbl. of capacity.
" " roof	0.03	" " " "
" " concrete lining	0.04	" " " "

The work was done by Mahoney Brothers, Allison and Cole, of San Francisco, with the writer acting as Superintendent of Construction. Mr. Earl Derby was Resident Engineer for the Kern Trading and Oil Company. Acknowledgment is made to Norman M. Halcombe, Assoc. M. Am. Soc. C. E., for help in preparing this paper.

DISCUSSION

C. P. Bowie,* Assoc. M. Am. Soc. C. E. (by letter).—The writer is much interested in this paper. He notes that the roof of the reservoir described was covered with roofing paper, on which was placed a layer of asphaltum and gravel. It has been his experience that such coverings, for receptacles used for the storage of oil, are very unsatisfactory and, at best, cannot be properly considered more than temporary. Mr. Bowie.

The average roofing paper is made by immersing an ordinary deadening felt (or similar material) in a solution of hot asphaltum and then passing the saturated sheet through a set of heavy rolls. In such a treatment the asphaltum not only adds to the quality of the body of the paper by toughening it, but also renders it, to a certain degree, impervious to water. The more volatile hydro-carbon compounds contained in crude oil pass off at comparatively low temperatures in the form of vapor, and their effect on these roofing papers is to "cut", as it were, the saturating material, so that in a short time the fibers of the paper, especially of that portion covering the cracks between the sheeting boards, are held together so loosely that they can be ruptured with ease by the pressure of the finger. It follows, then, that such roofings soon offer almost no resistance to the passage of gas formed by evaporation.

In the writer's opinion the proper covering for a storage reservoir, especially one in which crude oil for refining is to be kept, should be of steel plates, and "gas-tight". For this purpose, $\frac{1}{8}$-in. plates, which can be had in sizes 48 in. wide and in lengths up to 120 in., fastened together with $\frac{5}{16}$-in. rivets with $1\frac{1}{2}$-in. pitch, are ideal. In lieu of caulking, a thread weave (about $1\frac{1}{4}$ in. wide) which has previously been immersed in red lead, is placed between the laps of the sheets before riveting.

Near the center or highest point of such a roof, outlet pipes are placed, through which the gas can be drawn off, to be condensed or otherwise disposed of.

Regarding the loss by evaporation and the value of the product lost, to quote from the paper:

"A reservoir having a capacity of 750 000 bbl. loses 5% of oil per year, 1% of which is due to evaporation and 4% to seepage. In this case, 4% loss, at a value of 40 cents per bbl., represents an actual cash loss of $12 000 per year."

Assuming the losses by evaporation as stated by Mr. Cole to be correct; 1% of 750 000 bbl. would be 7 500 bbl., which product would be a material somewhat lighter than gasoline, probably between a gasoline

* San Francisco, Cal.

Mr. Bowie.

stock and casing head gas, and worth at the least consideration about 10 cents per gal., or $4.20 per bbl. The annual loss due to evaporation then would be $31 500 as compared with $12 000 lost by seepage; from which it would appear that an adequate covering for a reservoir is of more value than a concrete lining. This, of course, applies primarily to crudes which are to be used for refining purposes; however, considering the ever-increasing demand for gasoline and other refined products, it may be a matter of only a short time before necessity will require that only oils which have at least been topped, shall be sold for fuel purposes.

It is estimated that a steel roof for a reservoir costs about 2⅔ times as much as the present type of wooden roof covered with paper. Returning again to Mr. Cole's figures, this would make the cost per barrel for roof, say, 8 cents, as compared with 3 cents; or an increase of 5 cents per bbl. of capacity. The saving effected by the recovery of the oil which otherwise would be lost by evaporation, would then pay for such a roof in less than 1½ years.

Mr. Low.

EMILE LOW,* M. AM. SOC. C. E. (by letter).—The writer is very much interested in the method used in building up a compact and unyielding embankment in the construction of the oil-storage reservoirs described by Mr. Cole, and desires to record the method of building the earth embankments of the Hiland Avenue Reservoir of the new waterworks, at Pittsburgh, Pa., of which the late William H. Kennedy, M. Am. Soc. C. E., was Chief Engineer, the writer during the entire construction of this reservoir occupying various positions of responsibility.

The reservoir consists of two compartments (separated by an earth embankment), the larger one on the west and the smaller on the east side of Hiland Avenue. This street was closed and diverted, and its former site is now occupied by the division embankment. The site of the larger compartment had been occupied by market gardens, portions containing a deep, fertilized soil. The site of the smaller compartment had been covered by an apple orchard.

The reservoir is built on a comparatively level plateau overlooking the Allegheny River, just below the mouth of Negley's Run. The embankment extends around the entire periphery of the reservoir, except at the extreme western end, where, for a short distance, it is entirely in cutting.

The reservoir was to be partly in excavation and partly in embankment, and the first work was to clear the site of the embankment. In doing this, the rich top soil was first plowed, the loosened material being removed by two-horse scrapers and deposited immediately outside of the slope stakes. The underlying formation was generally clay.

* Buffalo, N. Y.

Mr. Low.

Cut-off ditches were then constructed, normal to the embankment slopes. These ditches were generally 8 ft. wide and from 2 to 4 ft. deep. They were excavated with plows and scrapers, and the removed material was placed on the cleared embankment site, which was first plowed, moistened, and rolled.

Owing to the large quantity of rich soil, much of which came from the market-garden plots, the outer slope of the embankment was built in an unusual manner. After the exact toe of the embankment had been fixed by slope stakes driven flush with the ground surface, the soil was deposited in a ridge about 2 ft. high, with a base about 6 ft. wide, carts being used for hauling.

Material from the cut-off ditches, and from the excavation inside the reservoir was placed next to this soil ridge in 6-in. layers, well watered, and rolled with a heavy cast-iron, grooved roller, drawn by two horses (or more after a rain). When the rolled embankment reached within 6 in. of the top of the ridge, more soil was deposited in a similar manner, great care being taken to have the outer surface conform to the prescribed slope, which was tested by level and measurement at frequent intervals. This method of placing the soil produced an interlocking effect. The specifications called for only 6 in. of soil, but the thickness actually averaged 12 in. or more, owing to the superabundance of this material.

The cut-off ditches previously referred to were refilled with suitable material, which was placed in thin layers, watered, and rolled. Care was taken to excavate these ditches below any roots.

In building the embankment, the lowest portions were filled first, care being taken to carry the layers up level, both longitudinally and transversely. On sloping ground the embankment was terraced or stepped, the cutting being usually 1 ft., the width depending on the slope. In transporting material from the excavation to the embankments, various methods were used. For short hauls near the embankments, two-horse scrapers were used. As the haul became longer, the scrapers were dumped into carts or wagons by drawing them over elevated timber platforms. Each platform had steep inclines and in the center there was a sliding trap door operated by hand. The filled scrapers were drawn up one incline, and after the team had passed the trap door, this was opened, the lip of the scraper was caught on a projection, and aided by the driver, this caused the scraper to turn over and deposit the material in the cart or wagon below, after which the team descended the other incline. Generally, the teams worked in a circle around each platform, and the latter was transported to another position whenever the limit of haul became too great.

Another method of excavation was effected with a machine, consisting of a large box, supported by two pairs of wheels, and drawn by three horses. This box held about 1 cu. yd. At the front end, there

Mr. Low. was a slat elevator, operated by cogs and pinions. At the bottom of the elevator there was a scoop-shaped plow. The material was loosened by this plow and then forced upon the elevator and carried into the box. When the latter was full, the scoop or plow was raised and the whole machine was hauled to the embankment.

The bottom of this box consisted of a number of hinged slats, which, when turned, allowed the material to drop out gradually, forming a layer of about 4 in. This machine was an ideal one for building the embankment, first on account of the thin and even layers deposited, and second, on account of the consolidation of the layers by the passage of the heavy loads over it. Notwithstanding this, rolling with the prescribed heavy grooved roller was never omitted, although it seemed at times to be a senseless requirement.

In excavating for the inner slope of the embankment, from 1 to 2 ft. of material was left undisturbed. As soon as the embankment reached this inner edge, the material was placed about 2 ft. inside the prescribed slope and also carried up steeper. The object of this was twofold: first, to obtain a solid embankment at the slope line; and second, to provide material for the puddle, which lined the inner slope from top to bottom.

The material on the site was generally clay, but there were quite large pockets of sand in the large compartment, and in its northern end there was also soft, sandstone rock, which latter was not allowed in the embankment, but was placed in spoil in an adjoining ravine.

Practically all the outer embankment was built of clay, a small quantity of sand being placed on the outer edge, and some intermingled with and deposited in thin layers at the same time as the clay.

In the division embankment the use of sand was allowed to a greater extent than in the outer embankment.

There was trouble from water in only one case, and this was where a spring issued near the outer edge of the northeastern embankment of the large compartment. This spring was merely walled in, and the water was carried off by an ordinary French drain.

In excavating at the south end of the eastern compartment quite a number of tile drains were unearthed. These passed under the site of the south embankment and emptied into a near-by ravine. In every case these drains were followed up and removed. The resulting excavations were roughened and widened, and then short cross-ditches were dug, all being refilled with suitable material, well moistened, and rammed by hand.

Water for moistening the embankment during construction and for other uses, was pumped from the Allegheny River, through a 1½-in. iron pipe, the pump being in one of the buildings of the Brilliant Oil Works, immediately above which the pumping station was under construction at the same time as the reservoir.

Mr. Reed.

RALPH J. REED,* ASSOC. M. AM. SOC. C. E. (by letter).—The remarkable growth of the petroleum oil industry in California during the past 15 years, shown in a most striking manner by the increase in annual production from 4 324 484 bbl. in 1900 to an estimated production of 103 000 000 bbl. in 1914, has resulted in the rapid development of facilities for handling and storing crude oils. By far the largest proportion of the crude oil stock of the State is stored in steel tanks, but there are in service, or ready for service, at the present time, 29 concrete-lined oil-storage reservoirs, having a total capacity of nearly 19 000 000 bbl. Reservoirs of this type are used largely for the storage of fuel oils varying in gravity from 14° to 18° Baumé. The lighter refining crudes, so far as the writer knows, are not stored in reservoirs, on account of the likelihood of large loss from the evaporation of the lighter and more valuable constituents, and on account of some uncertainty as to their effect on the concrete lining.

Some three or four years ago, when preparing to construct an oil reservoir, the writer had a search made in the Library of the Society for articles bearing on the subject. He was at that time unsuccessful in obtaining any information of value, and therefore welcomes Mr. Cole's paper, as it embodies a description of the latest practice in this type of construction.

It is the writer's opinion that the successful building of these reservoirs depends on a number of factors. Chief among these, as far as the earthwork is concerned, are the proper compacting of the material of the fill, and the careful building of the refill, both the bottom and the side slopes, so as to provide a uniform backing for the thin slab concrete lining. The "sheep's foot" or petrolithic rolling tamper is more successful than any other type of roller in building up a solid embankment, and the use of an ordinary road grader, to spread the material on the fill, and of a heavy disk harrow, to cut up clods of earth has proved helpful. The material of which the embankments of the reservoir at San Luis Obispo (referred to by Mr. Cole) are built, is a mixture of sand and heavy clay. The embankments built by the methods described appear to be nearly as well compacted as the ground on which they rest. The spreading of material in thin layers, and the use of as much water as possible without making the material too wet to work on, together with thorough tamping, have accomplished this result.

The method of trimming the excess material from the inner slopes, as developed by Messrs. Cole and Zeller, is extremely rapid and effective in bringing the inner slopes to line and grade with a minimum of hand work, to which it is so far superior, both in economy of labor and in results obtained, that it should be worthy of adoption on any similar earthwork where it is desired to finish a slope to accurate

* Los Angeles, Cal.

Mr. Reed.

dimensions. In order to minimize the effects of erosion on the outer slopes of the embankment, the practice of sprinkling the outer edge of the fill for a width of 6 or 8 ft. with heavy crude oil has been followed. This is done with a tank wagon equipped with a sprinkler pipe, and is carried on during the building of the fill. The oil tends to bind together the particles of material on the outer edge of the fill, and rainfall has little serious effect. Squirrels and gophers apparently dislike to burrow in oil-saturated soil, and thus the attacks of these rodents on the embankment are prevented.

It is believed to be easier and safer to erect the roof posts and girders from the floor with a derrick resting on the floor, than with a hand derrick from the fill or from the completed portion of the roof, as described by Mr. Cole. The small saw, driven either by an electric motor or a small gasoline engine, is a labor saver, when it is considered that about 220 000 ft., b. m. of sheathing, in 8 to 16-ft. lengths, must be laid, and that the number of sawn joints is large. The writer believes that Mr. Cole's statement regarding the erection of the roof by a force of 50 men in 7 days refers only to the erection of the posts, girders and rafters, which, in a reservoir of this size, would amount to about 300 000 ft., b. m. The force named would hardly be able to complete the entire roof in the time specified.

The erection of the roof prior to the pouring of the concrete lining is believed to be good practice and of importance, as it allows better control of the setting of the lining. Temperature changes are relatively small, and the lining, when carefully placed, shows little tendency even to small checks. Inspection of a recently completed reservoir, 18 days after pouring, showed practically no cracks in the bottom and about a dozen hair cracks on the entire slope. These were approximately at right angles to the intersection of the slope with the reservoir bottom, and extended up the slope from 5 to 15 ft. The writer has followed, with success, the Fuller-Thompson method of proportioning concrete, by mechanical analysis of the aggregates and construction of the curves to approximate the ideal curve, but he would use nothing larger than $\frac{3}{4}$-in. material in the mix for the floor, with $\frac{1}{4}$ to $\frac{3}{8}$-in. material for the side slopes.

Pouring the concrete lining on a 1:1 slope without forms, as Mr. Cole states, is not difficult, provided the earthen embankment has been well built, and shows no tendency to break down. The writer, however, would recommend the 1:1 inside slope only where the material to be handled contains a large percentage of clay. For embankments of sandy materials he would hesitate to recommend the 1:1 slope, but would prefer $1\frac{1}{2}$:1.

Expansion joints, of the type shown by Fig. 15, were used in the earlier reservoirs. They were constructed with a sheet of No. 20

gauge galvanized iron bent to the form shown, continuing from top to bottom of the reservoir, and placed so as to connect successive slabs of the concrete lining of the slope. In later reservoirs they have been omitted entirely, as they were in the case of the reservoir just referred to, which showed only twelve small cracks. It is the writer's belief that expansion joints are not necessary in work of this type, provided there is sufficient reinforcement in the slab and the concrete is carefully cured. Temperature variations are unusually small, especially when the reservoir is in service. Temperature observations in an empty reservoir for a short period are given in Table 1. The temperature of the oil in storage varies, during a period of one year, throughout a range of about 20°, the average temperature of oil in storage at San Luis Obispo being 60° Fahr. Mr. Reed.

Mr. Reed. The joint between the bottom and slope of reservoirs of this type has usually been constructed as shown in the illustrations accompanying Mr. Cole's paper. This is not designed as an expansion joint, as the reinforcing is carried through from slope to bottom, but it forms a convenient line to which to pour. As the writer believes that the small wooden form, of L cross-section, does not need to be left in place, he removes it before pouring the slope concrete.

With reference to the swing pipes on the inner ends of the outlets, it may be said that these are commonly used both in oil-storage tanks and in reservoirs. They allow the removal of oil from any level, and avoid the withdrawal with the oil of any water which may have collected at the bottom of the reservoir. They are incidentally of use when repairs are to be made to the controlling gate-valves.

The writer is inclined to agree with the statement of Mr. Bowie, that coverings of asphalt-saturated felt—the so-called roofing "paper"—are not satisfactory for the roofs of tanks used for the storage of the lighter refining oils. He does not find them unsatisfactory for the covering of tanks (or reservoirs) for the storage of fuel crudes or residua, though he admits that they are not usually gas-tight. For steel tankage, the $\frac{1}{8}$-in. steel-plate roof makes an excellent gas-tight covering, when the container is to be used for light refining crude oil, though, in his opinion, caulking the bevel-sheared edges of the plates is preferable to the insertion of a thread gasket saturated with red lead between the laps of the sheets. As was stated earlier in the discussion, few, if any, concrete-lined reservoirs are used for the storage of oils having volatile constitutents which are as valuable as those assumed by Mr. Bowie in his computation of the loss from evaporation.

Mr. Cole. E. D. COLE,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer must admit that Mr. Bowie is right in his contention that a wooden roof covered with ordinary roofing paper is rather poor construction when one considers the pains taken with the earthwork and concrete lining to make the reservoir oil-tight. However, as reservoirs of this type are intended at present only for storing fuel oil, and not the lighter grades which are used for refining purposes, the actual value of the oil lost by evaporation would be simply its market value as fuel. The writer believes that the lighter grades of oil can be stored successfully in concrete reservoirs, and that, eventually, this will be done, on account of the more economic type of construction. Then the roof specifications will no doubt be changed to include a covering which will be practically gas-tight.

Paper No. 1361

THE ECONOMICAL TOP WIDTH OF NON-OVERFLOW DAMS*

By William P. Creager, M. Am. Soc. C. E.

With Discussion by Messrs. Orrin L. Brodie, Edward Wegmann, and H. L. Coburn.

Synopsis.

This paper treats of the most economical width of top of the commonly-accepted type of section of solid, gravity, non-overflow dams. The writer believes it to be the general opinion of engineers that the section with a zero top width, namely, a triangular section, contains the minimum area consistent with fixed assumptions; and that the adoption of a definite width of top for a roadway or other purpose is made at a sacrifice of economy. Presumably, for this reason, many dams have been built with tops as narrow as 5% of the height. This investigation, however, shows, that the most economical width of top, for usual designing assumptions, is not zero, but lies generally between 10 and 17% of the height, according to the assumptions used in the design. As the difference in the volumes of sections, having quite a wide range of top widths, is very small compared with the uncertainty of many of the designing assumptions, the writer feels that many of his readers may consider this paper of academic rather than of economic interest.

* Presented at the meeting of January 5th, 1916.

It is just this point in particular, however, which the writer wishes to bring out, namely, that these investigations, as far as they have been carried, indicate:

1.—That there is little or no economy in the adoption of extremely narrow tops; and

2.—That exceptionally wide tops may be used, if desired, with comparatively little sacrifice of economy.

ASSUMPTIONS.

The curves shown on Fig. 1 cover seven sections, designed under different assumptions. They indicate for each the most economical width of top, in terms of height, and the relative areas of sections having other top widths. The assumptions used have been designated by letters, and are as follows:

Location of Resultant.—

A.—Resultant, reservoir full, to intersect all horizontal joints at the exact extremity of the middle third; except near the top before the down-stream face departs from the perpendicular, where the resultant lies within the middle third.

B.—Same as *A*, except to intersect at a point within the middle third a distance equal to one-fifteenth of the width of the joint.

C.—Resultant, reservoir empty, to intersect all horizontal joints at the exact extremity of the middle third; except near the top, before the up-stream face departs from the perpendicular, where the resultant lies within the middle third.

D.—Resultant, reservoir empty, to have no influence on the design of the section.

Forces Considered.—

E.—Weight of concrete; assumed specific gravity, 2.25.

F.—Weight of concrete; assumed specific gravity, 2.33.

G.—Horizontal component of water pressures.

H.—Vertical component of water pressures on the battered up-stream face.

I.—Horizontal silt pressure; silt assumed to be a liquid with a specific gravity of 0.64 in addition to the water pressure. Depth of silt five-tenths of the height of the section.

J.—Uplift on all horizontal joints. Total uplift assumed to be represented by a triangle, the unit uplift equal to five-tenths of the hydrostatic pressure due to the total head of water at the up-stream side diminishing uniformly to zero at the down-stream side.

Joint Pressures.—

K.—Limited to 9 tons per sq. ft., at the down-stream face.

L.—Limited to 11 tons per sq. ft. at the up-stream face.

M.—Joint pressures not considered.

Up-stream Face.—

N.—Battered to conform to Condition *C* only.

O.—Battered to conform to Condition *L* only.

P.—Vertical throughout.

CURVE NO. 1.

Assumptions A, D, E, G, M, and P.—In starting the investigation of this subject, a design was made for a section 200 ft. high, with a top width of 10 ft. The assumptions used in the design are indicated by the letters. This section, or any part thereof, can be changed to suit other heights by simply changing the scale to which it is drawn, as all weights and forces vary as the square of the height, and both the moment of stability and the moment of overturning vary as the cube of the height.

All the dimensions of the top 40 ft. of this section were then multiplied by 2.5, resulting in a section 100 ft. high, with a top width of 25 ft. The area of the resulting section was then computed as being the area of a dam 100 ft. high, with a top width of 25% of the height.

The top 50 ft. of the original section was then multiplied by 2.0, resulting in a section also 100 ft. high, but with a top width of 20% of the height.

In this way a number of sections were produced, each 100 ft. high, but having different widths of top. The relative areas are plotted on Curve No. 1 as ordinates and the top widths in percentages of the height as abscissas. (A typical set of calculations is given in the Appendix.)

It will be noted from this curve that the most economical top width of sections designed in accordance with these assumptions, is about 13.5% of the height.

CURVE No. 2.

Assumptions B, D, E, G, M, and P.—Curve No. 2 was prepared in the same manner and under the same assumptions as adopted for Curve No. 1, except that the resultant, reservoir full, instead of intersecting all horizontal joints at the exact extremity of the middle third (Assumption *A*), was required to lie within the middle third a distance of one-fifteenth of the width of the joint (Assumption *B*).

This curve, though slightly different in shape from Curve No. 1, also indicates the most economical width of top to be about 13.5% of the height.

CURVE No. 3.

Assumptions A, D, E, G, J, M, and P.—Curve No. 3 was derived under the same assumptions as those governing the design of Curve No. 1, except that uplift (Assumption *J*) at all horizontal joints was included. The total uplift was assumed to be represented by a triangle, the unit uplift equal to five-tenths of the hydrostatic pressure due to the total head of water at the up-stream side diminishing uniformly to zero at the down-stream side.

This curve indicates the most economical width of top for these conditions to be about 16% of the height.

CURVE No. 4.

Assumptions A, C, F, G, H, M, and N.—Curve No. 4 was prepared from a section, also designed in accordance with the assumptions used for Curve No. 1, except that in this case the specific gravity of the concrete was taken at 2.33 (Assumption *F*), instead of 2.25 (Assumption *E*), and the resultant was also required to intersect the base at the extremity of the middle third when the reservoir is empty (Assumption *C*). Assumption *C* necessitated a slightly battered up-stream face and the vertical component of the water pressure on this face was added to the forces acting (Assumption *H*).

In this case the most economical width of top appears to be about 12% of the height.

CURVE No. 5.

Assumptions A, C, F, G, M, and N.—Curve No. 5 is the same as Curve No. 4, except that the vertical component of the water pressure on the battered up-stream face (Assumption *H*) was neglected. In this case, alone, the most economical width was found to be zero,

but the curve is seen to be nearly horizontal between 0% and 14%, at the latter width involving an increase of material of only ½ of 1 per cent. This curve will apply directly to "Theoretical Type No. 2," by Edward Wegmann, M. Am. Soc. C. E., as it will be noted that the assumptions covering the design of the section are exactly the same as those used by Mr. Wegmann. It might be remarked here that the condition of requiring the resultant to lie within the middle third with reservoir empty is often omitted by engineers, a vertical up-stream face being adopted, unless a batter is required for the condition of limiting toe pressures.

Curve No. 6.

Assumptions B, D, E, G, I, M, and P.—Curve No. 6 was based on the assumptions used in preparing Curve No. 2, except that in this case silt pressure (Assumption *I*) was included. The silt pressure was assumed to be a liquid with a specific gravity of 0.64 in addition to the water pressure, and its depth was assumed as five-tenths of the height of the section.

On account of the silt pressure, the expedient of changing the scale, resorted to in computing previous curves, would apply from the top of the dam to the surface of the silt only. The rest of each section had to be computed separately for each point on the curve.

Assumption *I* seems to lead to a slightly larger economical top width, appearing on the curve to be about 15% of the height.

Curve No. 7.

Assumptions A, D, E, G, K, L, and O.—Thus far there has not been taken into consideration the condition of limiting joint pressures (Assumptions *K* and *L*). Curve No. 7 is based on these assumptions. In other respects the assumptions used were the same as for Curve No. 1.

On account of Assumptions *K* and *L*, the expedient of changing the scale, resorted to in computing Curves Nos. 1 to 5, would apply only from the top of the dam to the elevation at which the limiting joint pressures began to govern the design. The rest of each section had to be computed separately for each point on the curve.

The vertical component of the water pressure on the battered up-stream face (Assumption *H*) was neglected in order to simplify

the calculations. A comparison of sections 200 ft. high was also used in computing Curve No. 7.

For this curve the most economical width was found to be about 9% of the height. In all probability, to include in the calculations the vertical component of the water pressure on the battered up-stream face would increase the most economical width, as it was seen from Curves Nos. 4 and 5 that it resulted in an increase from 0 to 12 per cent.

Method of Application.

It must be remembered that the curves apply only to dams of constant height throughout their length. In order to obtain the greatest economy, the top width, theoretically, should be a fixed percentage of the height at any point. As a varying width of top is objectionable, for many reasons, a constant width should be adopted which will be somewhat less than that corresponding to the most economical for the maximum height, the amount of such reduction depending on the relative quantity of material contained in that portion of the dam less in height than the maximum.

In order to indicate the amount of such reduction the writer has designed a dam for the profile indicated on Fig. 1 in accordance with the assumptions used in computing Curve No. 3, and found the most economical top width for this dam to be 14% as compared with 16% indicated by Curve No. 3 for the maximum section (100 ft.).

This indicates that very little reduction in top width is necessary unless the variation in height of dam at different points along the profile is considerable.

Conclusion.

The assumptions used herein cover in a general way most of the important conditions usually considered, with the exception of ice thrust. However, as the consideration of overturning forces in addition to the water pressure seems to increase the most economical top width, as in the case of uplift and silt conditions (Curves Nos. 3 and 6); and as the consideration of ice thrust, in itself, increases greatly the top part of the section, it seems logical to assume that an economical top width for ice thrust condition would be at least as great as that indicated in Curves Nos. 3 and 6.

It is believed, therefore, that, except for Curve No. 7 (which, however, would probably have been similar to the rest if the vertical

component of the water pressure had not been neglected), practically no economy results in selecting a top width for dams of practically uniform height less than about 14% of the height; and that, for some designing assumptions, a width of even 17% involves no sacrifice of economy.

It is true that the assumptions on which these conclusions are based do not consider sliding or vertical shear. It is believed, however, that cases where these considerations affect the shape of the section are the exception rather than the rule. Moreover, in the light of these investigations, as far as they have gone, it is hard to say whether these conditions would require a smaller or a larger top width than indicated in the curves.

The writer regrets that he has not had the time to carry these investigations farther.

APPENDIX

Calculations for Curve No. 3.

Assumptions A, D, E, G, J, M, and P.—

Let:

H = The height of the dam above any horizontal joint, the length of which is to be determined;

L = The length of a horizontal joint to be determined;

L_0 = The known length of the horizontal joint next above;

h = The vertical distance between these two horizontal joints;

w = The weight of 1 cu. ft. of masonry = 140.5 lb.;

A = The resultant weight of the dam, above the known horizontal joint, divided by w; it is also equal to the area;

m = The horizontal distance from the heel of the dam to the resultant A;

P = The total water pressure on the up-stream face of the dam divided by w;

U = The total uplift pressure on the unknown joint divided by w;

s = The specific gravity of the masonry = 2.25;

M_P = The moment, about the heel, of water pressure on the up-stream face of the dam divided by w;

M_U = The moment, about the heel, of the uplift divided by w;

M_A = The moment, about the heel, of the weight of the dam divided by w.

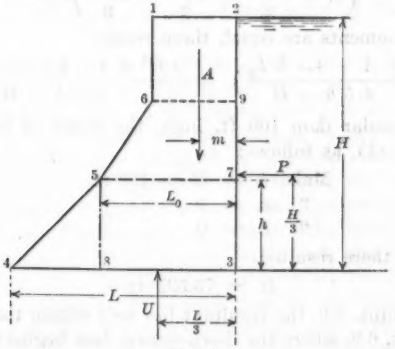

Fig. 2.

In the calculations, the weight of 1 cu. ft. of masonry was taken as unity; therefore the weight of 1 cu. ft. of water would be $\frac{1}{s} = \frac{1}{2.25}$.

The method of design, as worked out by Messrs. Morrison and Brodie, Wegmann, and others, was used.

A general formula to suit this particular case was first derived.

In Fig. 2 suppose the dam to have been already designed, down to the joint, 5-7. A general formula for the length, L, of the joint, 4-3, was derived as follows:

The weights and moments acting on the dam are given in Table 1.

TABLE 1.—WEIGHTS AND MOMENTS.

Portion.	Weight.	Moment about Point 3.
Masonry above joint 5-7.....	$+A$	$+A\,m$
Masonry in 5-7-3-8.....	$+L_0\,h$	$+\frac{L_0^2\,h}{2}$
Masonry in 4-5-8.....	$+\frac{L\,h}{2}-\frac{L_0\,h}{2}$	$+\frac{L^2\,h}{6}+\frac{L\,h\,L_0}{6}-\frac{L_0^2\,h}{3}$
Uplift, U.....	$-\frac{L\,H}{9}$	$-\frac{L^2\,H}{27}$
Horizontal water pressure, P..	Zero	$+\frac{H^3}{13.5}$

The total moment about Point 3 is:

$$A\,m+\frac{L_0^2\,h}{6}+\frac{L^2\,h}{6}+\frac{L\,h\,L_0}{6}-\frac{L^2\,H}{27}+\frac{H^3}{13.5}.$$

The reaction of the foundation is equal to the net weight of the dam, and the moment of the foundation reaction about Point 3 is the reaction multiplied by $\frac{2\,L}{3}$, or

$$\left(A+\frac{L_0\,h}{2}+\frac{L\,h}{2}-\frac{L\,H}{9}\right)\frac{2\,L}{3}.$$

As these two moments are equal, there results:

$$L^2+L\left(\frac{18\,A+4.5\,h\,L_0}{4.5\,h-H}\right)=\frac{2\,H^3+4.5\,L_0^2\,h+27\,A\,m}{4.5\,h-H}\ldots.(1)$$

For a triangular dam 100 ft. high, the width of base was found from Equation (1), as follows:

Make $h = H = 100$ ft.
" $A = 0$
" $L_0 = 0$

Solving for H, there resulted:

$$H = 75.592 \text{ ft.}$$

Above the joint, 6-9, the resultant lies well within the middle third, and at the joint, 6-9, where the down-stream face begins to depart from the vertical, it is just at the extremity of the middle third. In order to find the height, 1-6, of this portion, the following assumptions for substitution in Equation (1) were made:

$A = 0$
$L_0 = L = 10$ ft., the width of top,
$h = H$

Solving for H, there resulted:

$$H = 13.229 \text{ ft.}$$

To find the length, L, of a joint 16 ft. from the top, the dam was assumed to have been designed, as indicated above, down to an elevation 13.229 ft. from the top. For this case:

$$\begin{aligned} L_0 &= 10 \\ A &= 13.229 \times 10 = 132.29 \\ m &= \frac{10}{2} = 5 \\ H &= 16 \\ h &= 16 - 13.229 = 2.771 \end{aligned}$$

With these substitutions in Equation (1), there resulted: $L = 11.10$ ft. The area and all other characteristics of the section from the top to an elevation 16 ft. from the top were then calculated. For the length of the joint 20 ft. from the top, the following substitutions in Equation (1) were made:

$$\left.\begin{aligned} L_0 &= 11.10 \\ A &= 161.52 \\ m &= 5.280 \end{aligned}\right\} \text{(from the foregoing)}$$

$$\begin{aligned} H &= 20 \\ h &= 20 - 16 = 4 \end{aligned}$$

With these substitutions, there resulted: $L = 13.06$ ft.

In this way, the whole section was designed by successive steps to an elevation 200 ft. from the top. A summary of the calculations is given in Table 2.

The next step was to derive from Table 2 a number of other sections, each 100 ft. high, but having different top widths. Columns 1 and 6 of Table 2 are repeated on Lines 1 and 2 of Table 3. A section of this type of any height can be adapted to any other height by simply changing the scale to which it is drawn, as the weights and water pressures are all functions of H^2, and the moments of the weight of masonry and water pressures are functions of H^3. This was done in Table 3. The heights and top widths indicated on Lines 1 and 3 were multiplied by the factors on Line 4, and entered on Lines 6 and 8, respectively. The new heights were all 100 ft.

The areas on Line 2 were multiplied by the square of the multiplying factor to give the new areas entered on Line 7.

The top width, as a percentage of the height given on Line 9, was obtained by dividing the quantities on Line 8 by the corresponding quantities on Line 6 and multiplying by 100 to obtain the percentages.

Calling the minimum area on Line 7 equal to 1.0, the other areas, in terms of this one, were found and entered on Line 10.

The quantities from Line 10, as ordinates, and the corresponding quantities from Line 9, as abscissas, were used in plotting Curve No. 3.

* Triangular dam.

DISCUSSION

Mr. Brodie.

ORRIN L. BRODIE,* M. AM. SOC. C. E.—The author has indicated the range in the economic top width of non-overflow dams as varying from about 10% to a little more than 17% of the height, according to the assumptions of design. Such discussion, if academic, as the author fears, is not without value if it helps in any way to fix the ideas.

The lower limit of 10% has been recognized for some time as of practical value; but, in connection therewith, the factors affecting width, besides pure economy, should not be neglected. The speaker refers to requisite width of roadway across the top of the dam, drainage wells within the body of the structure, and upper inspection gallery in a longitudinal direction, all of which require space which in large part often governs in fixing a top width. Incidental to some of the above should be mentioned the architectural treatment of railing or parapet, which is also closely related to the coping and cove stones or blocks, space for which must be provided at the top of the dam and so as not to encroach on the interior passageways, if any, at the top.

The author expresses a belief that the prevailing opinion of engineers is that the triangular dam (presumably with the apex at the water surface) provides the minimum section for fixed assumptions. Although the triangular section is theoretically fitted to withstand a horizontal liquid pressure intensity, increasing downward from zero at the top, the speaker seriously doubts that such general opinion prevails, for, unless he is much mistaken, it must be obvious to any one having to deal with the design of dams, especially high ones, that there is no economy in a triangular profile, in all cases, over one with a wider top, for the superimposed weight of the latter would result in correspondingly shorter bases in the lower portion than would obtain for a triangular cross-section. Furthermore, where uplift is considered active, it should be remembered that its tendency to overturn the structure is a function of the length of base.

The speaker noted the omission of consideration of ice pressure in the studies presented, except for passing mention. A study of its effect on the percentages deduced, should prove interesting.

As nothing is stated in the paper concerning the superelevation of the top of the dam, it is to be doubtless inferred that the top in each case was taken flush with the water surface.

At the risk of being tedious, perhaps, the speaker will continue his discussion, also in a way that may be said to be somewhat academic; but, to illustrate what effect on the cross-section consideration of ice pressure and of superelevation of the top has, and to compare ordinary sections with the triangular, four cross-section designs, *A*, *C*, *F*, and

* New York City.

Mr. Brodie.

D, have been prepared, the base of each of which is subject to a head of 100 ft., the top in every case except the triangular dam, *D*, being 10 ft. wide.

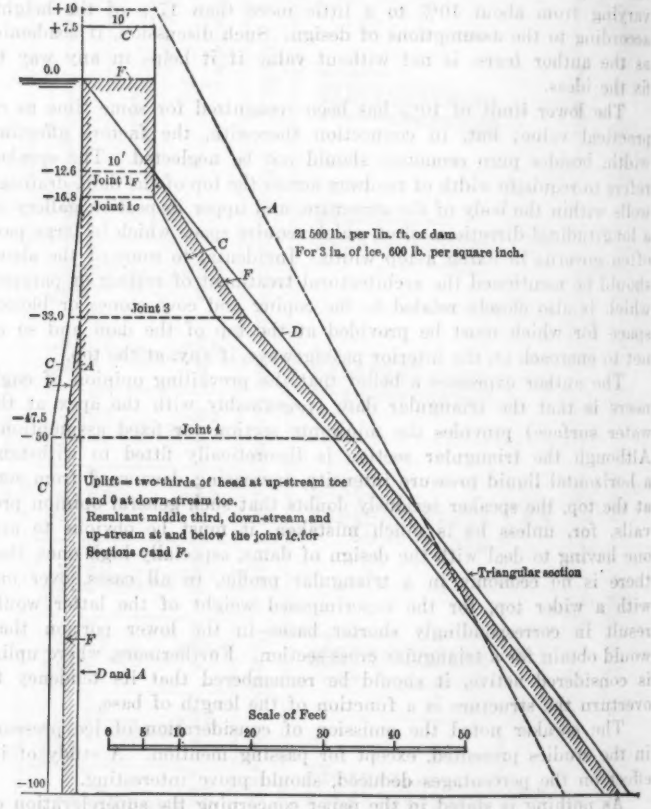

FIG. 3.

The method of design is identical with that outlined previously* by the speaker. In fact, two of the cross-sections were taken from the earlier discussion and extended.

A is designed for 21 500 lb. per lin. ft. of dam, ice pressure at water surface; uplift intensity in joint of two-thirds of the head at the

* In discussion of "Provision for Uplift and Ice Pressure in Designing Masonry Dams", by the late C. L. Harrison, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 174.

Mr. Brodie.

up-stream edge of each joint, diminishing to zero at the down-stream edge, and the horizontal thrust of the water. The relative density of the masonry is assumed at 2¼. The resultant is nowhere outside of the middle-third limit of the joint in question.

The same conditions, with the exception of ice pressure, apply to the other three sections.

Section *A*, as brought out in the discussion previously referred to, required a superelevation and top width of at least 10 ft., that is, no practically satisfactory cross-section resulted from the analytic design with lower values for the top width and superelevation.

Section *C* was assumed to have a superelevation of 7.5 ft., and Sections *F* and *D* have their tops at the reservoir surface.

In comparing these sections, note how the down-stream face of the triangular section (*D*'s) is everywhere down stream or exterior to the respective faces of Sections *F* and *C*. Similarly, *F*'s face is exterior to *C*'s. This shows, in part, the effect on the cross-section of the superelevation (*C*) and sensible top width of the dam (*F*).

With regard to the up-stream faces, however, it is to be noticed that where *C*'s down-stream face was the innermost, it is now the outermost, with respect to the sections. *F* is still intermediate with respect to the positions of *D*'s and *C*'s up-stream faces.

The ice-pressure section, it will be observed, encroaches within the other sections toward the bottom.

Table 4 gives the areas and bases, etc., of the cross-section for depths of 50 and 100 ft.

TABLE 4.

Cross-section.	Conditions.	50 Ft. Depth of Water.		100 Ft. Depth of Water.			
		Area, in square feet.	Base, in feet.	Area, in square feet.	Top width, in feet.	Superelevation, in feet.	Base, in feet.
A.....	Ice, horizontal and upward.	.....	....	4 375	10	10	69.0
C.....	Horizontal and upward.....	999.0	39.5	3 969	10	7.5	79.3
F.....	Horizontal and upward.....	998.0	40.0	3 973	10	0	79.0
D.....	Horizontal and upward.....	992.5	39.7	3 970	0	0	79.4

Ice = 21 500 lb. per lin. ft. of dam.
Uplift = two-thirds of the head at the up-stream edge of the joint, decreasing uniformly to zero at the down-stream edge.
Specific gravity of masonry = 2¼.

Turning attention now to the quantities of masonry involved, the result presents itself that, save for the ice-pressure section, *A*, all the sections are practically of the same volume, therefore it may be concluded that, for a given width, the superelevation affects, not the quantity of material, but only its distribution in the cross-section.

The quantity of material in the cross-section would seem to depend on the top width, to a certain extent; but more on the forces assumed

Mr. Brodie. to be acting on the dam. Although the superelevation thus has its effect on the shape of the cross-section, the practical questions of rise of reservoir due to flood, wave height, etc., determine in large part what superelevation is desirable.

Mr. Wegmann. EDWARD WEGMANN,* M. AM. SOC. C. E. (by letter).—The author has discovered the interesting fact that, for a dam of the type shown in Fig. 4, there is a certain top width which gives the most economical section. One would suppose that the narrower the top width, the smaller would be the area of the profile. Mr. Creager has proved that such is not the case, and the method by which he found the top width giving the most economical profile, is correct, provided he does not insist on a rigid compliance with the usual requirement that the lines of pressures, reservoir full or empty, shall be kept within the center-third of the profile.

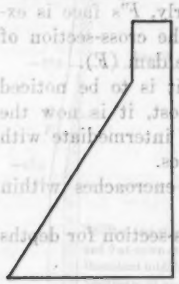

FIG. 4.

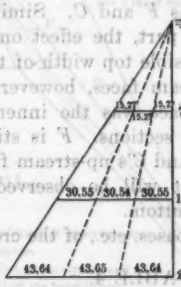

FIG. 5.

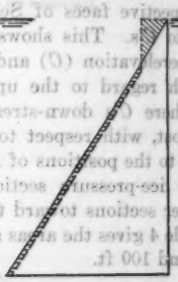

FIG. 6.

Fig. 5 shows a triangular profile without any top width, which is designed to resist solely the hydrostatic pressure of the water, no attention being paid to shocks from floating bodies or from waves. Upward pressure is not considered in this case. In this profile the lines of pressure, for reservoir full and empty, are, respectively, on the down-stream and up-stream limits of the center-third of the profile, and the latter has, therefore, the minimum area which will comply with the given conditions.

If, however, a thin slice of masonry is cut from the down-stream face of the dam, and placed as a small inverted triangle at the top of the dam, as shown by the shaded area in Fig. 6, it will be found that the dam has been strengthened, even though the width of its base has become slightly less, as the moment around its toe is greater for the small inverted triangle than for the thin slice of masonry. In this case, therefore, there is a surplus of strength, and the area of the profile can be reduced slightly.

* New York City.

Mr. Wegmann.

There is, however, a limit to the thickness of the slice of masonry which can be transferred from the front face to the top of the dam, as Mr. Creager has shown. The top width which gives the most economical profile can probably be determined by the differential calculus.

Although it is true that one can obtain, in this manner, a profile (Fig. 6), which has less area than the simple triangular profile (Fig. 5), it does not comply strictly with the given condition for reservoir empty. The effect of the small inverted triangle placed at the top of the dam, is to draw the line of pressure, reservoir empty, slightly outside of the center-third. The extent to which this is done is of no practical importance, but the fact remains that, for the given conditions, the triangular profile (Fig. 5) has the minimum area.

If Mr. Creager's rule for the least top width is applied in the design of a dam, this width will have to vary from one end of the dam to the other, according to the height of the structure. This, of course, would never be done in actual practice. Usually, the top width of a masonry dam is not to be determined by theoretical principles, but by practical considerations, such as the strength required to resist shocks from waves or floating bodies, the breadth needed for a roadway over the top of the dam, etc.

Mr. Coburn.

H. L. COBURN,* M. AM. SOC. C. E. (by letter).—This paper was read with much interest by the writer as he had made a study of the same problem, some time previously, but along somewhat different lines. Like Mr. Creager, the writer is not sure that the presentation is of much more than academic interest, but it may give some indication as to why different designers, starting from similar premises, reach such apparently different results in designing the cross-section of a masonry dam.

The writer's method of attack is shown in the accompanying computations, and the results are given in both tabular and graphical form.

The assumptions were as follows:

Specific gravity of masonry 2.3; upward pressure over entire base, varying uniformly from that due to full hydrostatic head at heel to zero at toe; resultant of all forces, reservoir full, must cut base at one-third its length from the toe, that is, there must be no stress at extreme up-stream edge of base. This, of course, assures the minimum section allowable, if the masonry is assumed to have no tensile strength.

The section assumed is made of two right-angle triangles, the fillet which usually would be provided at the junctions of the two triangles in the down-stream face being considered as negligible.

For convenience in making the computations, the width of top was taken in terms of width of base rather than of height, and was

* New York City.

Mr. Coburn.

expressed by $b = B \div k$; the width of the base was then calculated for various values of k. It should be noted that, for all values of k greater than about 2.6, or top less than 0.4 of the base, or 0.3 of the height, there is only a small variation in the area of the cross-section, with the area a minimum, when the top is about 0.25 of the base or 0.2 of the height. For this section, the base is 0.81 of the height. The average pressure on the base, with reservoir full, is 45 H, in pounds per square foot, and the maximum at the toe is twice this, or 89 H, in pounds per square foot. With the reservoir empty, the average pressure will be 76 H; the maximum at the heel will be 157 H, and the minimum at the toe -4.5 H. Indeed, it should be noted that, with a vertical up-stream face and any width of top greater than zero and less than one-half the base, there will always be some tension at the toe when the reservoir is empty, but this will usually be negligible.

It is of interest, also, to note that, for all widths of top less than one-half, the ratio of horizontal to vertical forces is very high, indicating the necessity of great care in providing means to prevent sliding.

TABLE 5.—FUNCTIONS OF SECTION, IN TERMS OF HEIGHT, FOR VARIOUS WIDTHS OF TOP, ASSUMING UPWARD PRESSURE ON BASE VARYING UNIFORMLY FROM FULL HYDROSTATIC HEAD AT HEEL TO ZERO AT TOE.

k = Ratio of base to top;
r = " " top to base = $\frac{1}{k}$;
R = " " " " height;
C = " " base to height, $B = CH$;
A = Area of cross-section, in terms of square of height, area = AH^2
P_1 = Average pressure on base, reservoir full, in terms of height, $P_{av.} = P_1 H$
P_2 = " " " " " empty " " "
P_3 = Maximum " at heel " " " " "
P_4 = Minimum " at toe " " " " "
F = Ratio of horizontal to vertical forces.

All in pounds per square foot.

Inspection of Table 5 will make it clearly apparent that, with a simple triangular section, that is, zero width of top, a dam so designed will be equally stable at all portions, regardless of height, and the stresses in the masonry and on the foundations will be a maximum

Mr. Coburn.

at the greatest section. It is equally apparent that, with a top of any considerable width, a dam, having a maximum section designed in accordance with these figures, will be least stable at its point of greatest height where the resultant will just cut the middle-third.

Consider the section as made up of two triangles, as shown in Fig. 7, the fillet at a being negligible.

Assume an upward pressure on the base equal to the full hydrostatic head at the heel, decreasing uniformly to zero at the toe.

The resultant, with reservoir full, is to cut the base at the down-stream one-third point; that is, no stress at the heel.

The problem is to find the width of the base, B, in terms of the height, H, with varying widths of the top, $b = B \div k$.

Take moments about the down-stream one-third point, as ΣM about this point must equal 0 to meet conditions imposed.

FIG. 7.

$$\text{Moment of horizontal pressure} = \frac{w\,H^2}{2} \times \frac{H}{3} = \frac{w\,H^3}{6}$$

$$\text{Moment of upward pressure} = \frac{w\,H\,B}{2} \times \frac{B}{3} = \frac{w\,H\,B^2}{6}$$

$$\text{Moment of weight of lower triangle} = \frac{2.3\,w\,H\,B}{2} \times \frac{B}{3} = \frac{2.3\,w\,H\,B^2}{6}$$

$$\text{Moment of weight of upper triangle} = \frac{2.3\,w\,h\,b}{2} \times \left(\frac{2\,B}{3} - \frac{2\,b}{3}\right) = \frac{4.6\,w\,H\,B^2}{6}\left(\frac{k-1}{k^3}\right)$$

$$\Sigma M = H^3 + H\,B^2 - 2.3\,H\,B^2 - 4.6\,H\,B^2\left(\frac{k-1}{k^3}\right) = 0$$

$$B = H\left(1.3 + 4.6\,\frac{k-1}{k^3}\right)^{-\frac{1}{2}} = C\,H \ldots\ldots\ldots\ldots (1)$$

Second.—Area of cross-section in terms of height:

$$A = \frac{1}{2}(B\,H + b\,h) = \frac{1}{2}\left(C\,H^2 + \frac{C\,H^2}{k^2}\right) = \frac{C\,H^2}{2}\left(1 + \frac{1}{k^2}\right) \ldots (2)$$

Third.—Pressure on base, reservoir full: (From the conditions imposed, maximum at the toe, 0 at the heel).

Take moments about the center of gravity of the base:

$$\text{Moment of horizontal pressure} = \frac{w\,H^2}{2} \times \frac{H}{3} = \frac{w\,H^3}{6}$$

$$\text{Moment of upward pressure} = \frac{w\,H\,B}{2} \times \frac{B}{6} = \frac{w\,H\,B^2}{12}$$

Mr. Coburn.

Moment of weight of lower triangle $= \frac{2.3\,w\,H\,B}{2} \times \frac{B}{6} = \frac{2.3\,w\,H\,B^2}{12}$

Moment of weight of upper triangle $= \frac{2.3\,w\,h\,b}{2} \times \left(\frac{B}{2} - \frac{2\,b}{3}\right) = \frac{2.3\,w\,H\,B^2}{12}\left(\frac{3\,k-4}{k^3}\right)$

Reaction $= P_{av.}\ B \times \frac{B}{6} = \frac{P_{av.}\ B^2}{6}$

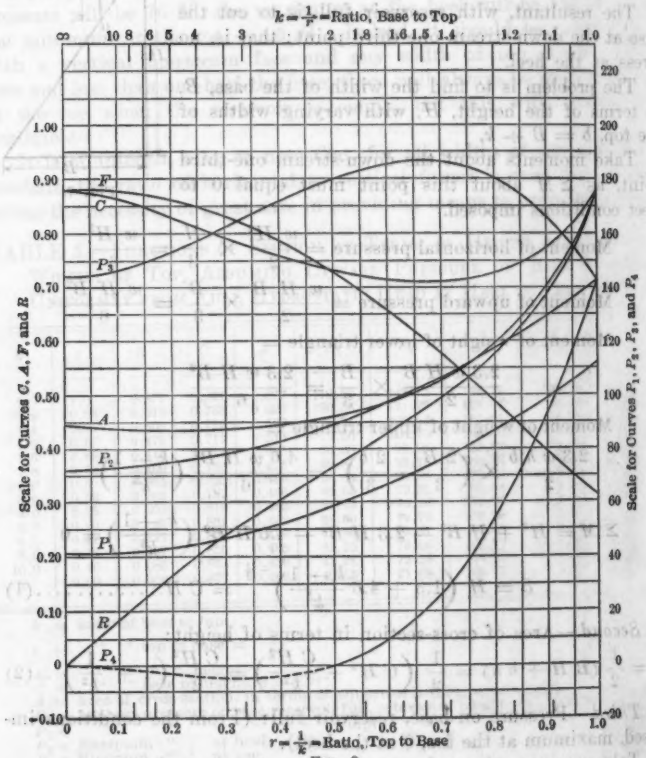

FIG. 8.

Equate, multiply by 6, and divide by B^2, and we get

$$P_{av.} = w\,H\left[\frac{1}{C^2} + \frac{1}{2} - 1.15\left(1 + \frac{3\,k-4}{k^3}\right)\right] = P_1\,H \ldots . (3)$$

$P_{max.}$ = twice $P_{av.}$

Mr. Coburn.

Fourth.—Pressure on base, reservoir empty:
Take moments about the center of gravity of the base.

Moment of weight of lower triangle =

$$\frac{2.3\,w\,H\,B}{2} \times \frac{B}{6} = \frac{2.3\,w\,H\,B^2}{12}$$

Moment of weight of upper triangle =

$$\frac{2.3\,w\,H\,B}{2\,k^2}\left(\frac{B}{2} - \frac{2\,B}{3\,k}\right) = \frac{2.3\,w\,H\,B^2}{12}\left(\frac{3\,k-4}{k^3}\right)$$

$$\Sigma\,W = \frac{2.3\,w\,H\,B}{2}\left(1 + \frac{1}{k^2}\right); \quad \Sigma\,M = \frac{2.3\,w\,H\,B^2}{12}\left(1 + \frac{3\,k-4}{k^3}\right).$$

$$\text{Moment of arm of resultant} = \frac{\Sigma\,M}{\Sigma\,W} = \frac{B}{6}\left(\frac{k^3+3\,k-4}{k^3+k}\right)$$

or
$$e = \frac{C\,H}{6}\left(\frac{k^3+3\,k-4}{k^3+k}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Now, the average pressure on the base $= \Sigma\,W \div B$

$$= P_2\,H = \frac{2.3\,w\,H}{2}\left(1 + \frac{1}{k^3}\right) = 1.15\,w\,H\left(1 + \frac{1}{k^3}\right) \ldots (5)$$

$$P_3 = (P_{max.}) = P_2\left(1 + \frac{6\,e}{B}\right) = 1.15\,w\,H\left(1 + \frac{1}{k^3}\right)\left(1 + \frac{k^3+3\,k-4}{k^3+k}\right)$$

$$= 2.3\,w\,H\left(\frac{k^3+3\,k-2}{k^3}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

$$P_4 = (P_{min.}) = P_2\left(1 - \frac{6\,e}{B}\right) = 1.15\,w\,H\left(1 - \frac{1}{k^3}\right)\left(1 + \frac{k^3+3\,k-4}{k^3+k}\right)$$

$$= 2.3\,w\,H\,\frac{2-k}{k} \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

Fifth.—Ratio of horizontal to vertical forces:

$$F = \Sigma\,H \div \Sigma\,V$$

$$= \frac{w\,H^2}{2} \div \left(\frac{2.3\,w\,H\,B}{2} + \frac{2.3\,w\,H\,B}{2\,k^2} - \frac{w\,H\,B}{2}\right)$$

$$= \frac{H}{B}\left(\frac{k^2}{1.3\,k^2 + 2.3}\right) = \frac{1}{C}\,\frac{k^2}{1.3\,k^2 + 2.3} \quad \ldots\ldots\ldots\ldots (8)$$

Paper No. 1362

THE CHERRY STREET BRIDGE, TOLEDO, OHIO*

By Clement E. Chase, Jun. Am. Soc. C. E.

With Discussion by Messrs. Edward Godfrey, James Ritchie, and Clement E. Chase.

Synopsis.

This paper describes the general design and the most interesting and instructive features of the construction of a massive reinforced concrete arch bridge across the Maumee River at Toledo, Ohio.

After a short résumé of the history of the former bridge at this site and of the new bridge project, the loadings and general features of the design are stated. The construction work is followed in some detail from its beginning in 1910 to the opening for use of the first half of the structure during the winter of 1912-13. The construction of the second half of the bridge, being to all intents a duplication of the work on the first half, is merely outlined up to January 1st, 1914, at which time the structure was practically complete.

The description of construction deals with the following features: The building of the bridge in parallel halves, carrying traffic on the old structure at the same time, until the first half was completed; the use of deep, single-wall coffer-dams and attempts to dig wells to rock from the bottom of the pumped-out dams by the Chicago method; change of plans by reason of the proven hazard of this first plan, and the utilization of steel cylinders sunk inside the unwatered dams; the

* Presented at the meeting of December 1st, 1915.

filling of these cylinders with concrete and the sealing of the coffer-dams by concrete deposited under water; the construction plant and methods of depositing concrete under water, with a statement of the general principles; the collapse of a steel coffer-dam, through failure of the bracing, and its repair and re-use; the use of movable steel centers to support the arch concrete, and the expedients resorted to for increasing the width (of the arch barrel) poured at one time; the forms, plant, and methods of work in building the arches, spandrel walls, and viaduct; the procedure followed in water-proofing and back-filling; and the erection of the bascule span. Special attention is paid to the esthetic appearance of the bridge. The paper closes with a summary of unit prices, quantities, and amounts expended for the different parts of the work.

Historical.

The main portion of the City of Toledo, Ohio, is separated from an important industrial and residential section, known as East Toledo, by the Maumee River, across which, from the earliest history of the community, the Cherry Street Bridge has been the main thoroughfare. Following several predecessors—of types corresponding to the progress of the art of bridge building in the United States—the iron structure, which has been recently replaced, served to carry the growing traffic across the river from 1883 until January, 1913. Several years before that time, it was realized that the bridge was inadequate for the constantly increasing loads which it had to carry, and that, with the larger number of lake carriers docking above its site, a more rapid form of movable span was needed than the existing swing span. The question of type and location for the new bridge was debated heatedly, at great length, and with such intense partisanship that the whole project was held up for a long period. The main points at issue were finally settled—the new structure should be of concrete, with a double-leaf lift-span across the channel, and should cross the river, as before, at Cherry Street.

Design.

As finally located, the south half of the new and much wider structure covers the site of the old one. For a time it was planned to construct temporary piers alongside the old ones and shift the

spans sideways so as to clear the bridge site. Later, this plan was abandoned, largely on account of anticipated danger from ice, and it was decided to build the new bridge in longitudinal halves. The north portion was to be completed first, the old bridge was then to be removed, and finally the arches were to be extended to their full width of 73 ft. 10 in. The width of Cherry Street is maintained practically unchanged as it passes over the bridge, the roadway being 52 ft. between curbs and the sidewalks 9 ft. wide. Two car tracks are provided in the center of the roadway.

There is a clear channel opening of 200 ft., closed by a double-leaf bascule span. Approaching this, the roadway has a grade of 2.02% from the east and 1.35% from the west, which gives enough elevation at the bascule to allow a clearance of 29 ft. under the steel, with span closed. This is quite enough to pass the tugs and "sandsuckers" which caused a considerable percentage of the openings of the old draw-span. Maintaining river traffic through both bridges during the construction of the new one, required the layout of the new channel as shown on Fig. 1, so that in order to open it, the old draw might be swung one way until the new bridge should go into commission. Fig. 1 also shows the layout and principal dimensions of the arch openings. To the east of the channel there are five spans, decreasing in length from 108 ft. to 66 ft. 6 in. and in rise from 28 ft. 6 in. to 16 ft., in order to conform to the grade. To the west there are two more of the 108-ft. arches—the grade here being taken care of by dropping both ends of the arch nearest the shore by 1½ ft. These 108-ft. arches have a thickness of 7 ft. at the springing line and 2 ft. 3 in. at the crown. Their intrados is an ellipse with a semi-major axis of 54 ft. and a semi-minor axis of 29 ft. Fig. 2 gives the dimensions of the various arch rings. The assumptions of load used in the design include a sand fill weighing 100 lb. per cu. ft.; 50-ton interurban cars in trains on both tracks, each covering a width of 10 ft.; and a live load of 150 lb. per sq. ft. on the remainder of the roadway and of 100 lb. per sq. ft. on the sidewalks. A maximum stress in the concrete of 450 lb. per sq. in. was specified, and a temperature range of 70° was assumed. The reinforcement consists of latticed ribs, 2 ft. 6 in. from center to center, and transverse rods, along the extrados and intrados, 3 ft. apart.

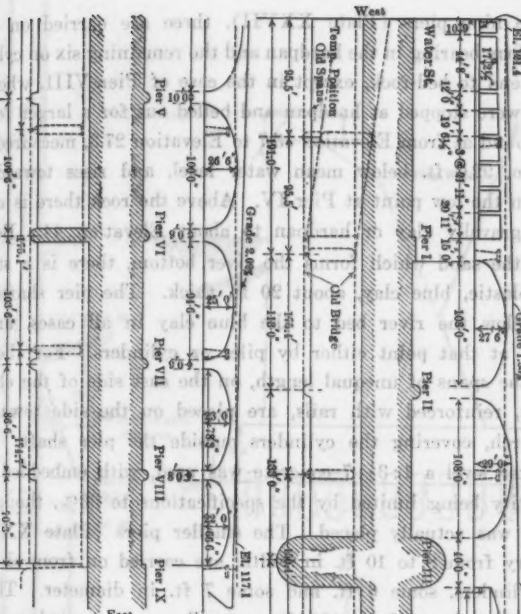

FIG. 1.

CHERRY STREET BRIDGE, TOLEDO, OHIO.
GENERAL PLAN OF OLD AND NEW STRUCTURES.

Of the nine piers (Plate XXVII), three are carried on piling driven to firm bearing in the hardpan and the remaining six on cylinders which extend to bed-rock, except in the case of Pier VIII, where the cylinders were stopped at hardpan and belled out for a larger footing. Rock is found at from Elevation 13.7 to Elevation 27.3, measured from the datum, 92.0 ft. below mean water level, and rises toward each shore from the low point at Pier IV. Above the rock there is a layer of hard, gravelly clay or hardpan to about Elevation 44. Between this and the sand which forms the river bottom, there is a stratum of soft, plastic, blue clay, about 20 ft. thick. The pier shafts were carried below the river bed to the blue clay in all cases, and are supported at that point either by piles or cylinders. For the piers between the spans of unequal length, on the east side of the channel, buttresses, reinforced with rails, are placed on the side toward the smaller arch, covering the cylinders outside the pier shaft. Below mean water level a 1:3½:7 concrete was used, with embedded stone, the quantity being limited by the specifications to 33%, though less than this was actually placed. The smaller piers (Plate XXVIII), which vary from 8 to 10 ft. in width, are carried on from eleven to twelve cylinders, some 6 ft. and some 7 ft. in diameter. The two large bascule piers, 40 by 126 ft. over all, are supported on eleven cylinders, 9 ft. 6 in. in diameter. The two abutment piers, I and IX, are carried on piles, 3 ft. from center to center and 25% of these piles are driven to a 2 in 12 batter. Pier II, which has a 108-ft. arch on each side, is carried on 370 piles, supporting a 24 by 105-ft. footing.

The construction of the bridge in longitudinal halves necessitated a central spandrel wall to retain the fill in the north half until the completion of the whole bridge. For this, a reinforced concrete wall, 18 in. thick, with counterforts 9 ft. from center to center, was designed. The outside spandrel wall was shown on the original plans —on which the contractor's bid was based—as a gravity section. and was built with a base forty-two one-hundredths of the height and a fixed top width of 1 ft. 6 in. The back surface of the wall is warped, as the batter changes constantly, but this caused very little difficulty in forming. A tile conduit to carry power and lighting cables across the bridge rests on a reinforced concrete slab supported under the sidewalks by brackets built into the outer spandrel wall.

CONDITIONS.
CHERRY STREET BRIDGE,
TOLEDO, OHIO.

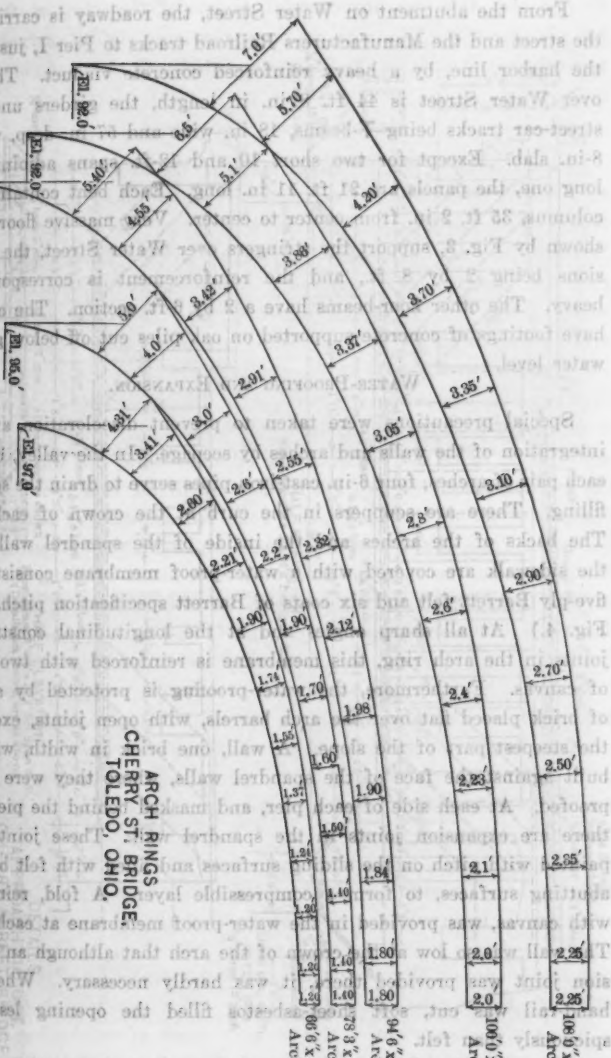

FIG. 2.—ARCH RINGS CHERRY ST. BRIDGE, TOLEDO, OHIO.

From the abutment on Water Street, the roadway is carried over the street and the Manufacturers Railroad tracks to Pier I, just inside the harbor line, by a heavy reinforced concrete viaduct. The span over Water Street is 44 ft. 8 in. in length, the girders under the street-car tracks being T-beams, 18 in. wide and 57 in. deep, with an 8-in. slab. Except for two short 10 and 12-ft. spans adjoining the long one, the panels are 21 ft. 11 in. long. Each bent contains three columns, 35 ft. 2 in. from center to center. Very massive floor-beams, shown by Fig. 3, support the stringers over Water Street, the dimensions being 2 by 8 ft., and the reinforcement is correspondingly heavy. The other floor-beams have a 2 by 6-ft. section. The columns have footings of concrete supported on oak piles cut off below ground-water level.

Water-Proofing and Expansion.

Special precautions were taken to prevent discoloration and disintegration of the walls and arches by seepage. In the valley, between each pair of arches, four 6-in. cast-iron pipes serve to drain the spandrel filling. There are scuppers in the curb at the crown of each arch. The backs of the arches and the inside of the spandrel wall up to the sidewalk are covered with a water-proof membrane consisting of five-ply Barrett felt and six coats of Barrett specification pitch. (See Fig. 4.) At all sharp angles and at the longitudinal construction joints in the arch ring, this membrane is reinforced with two layers of canvas. Furthermore, the water-proofing is protected by a layer of brick placed flat over the arch barrels, with open joints, except in the steepest part of the slope. A wall, one brick in width, was also built against the face of the spandrel walls, where they were water-proofed. At each side of each pier, and masked behind the pier face, there are expansion joints in the spandrel wall. These joints were painted with pitch on the sliding surfaces and filled with felt between abutting surfaces, to form a compressible layer. A fold, reinforced with canvas, was provided in the water-proof membrane at each joint. The wall was so low at the crown of the arch that although an expansion joint was provided there, it was hardly necessary. Where the hand-rail was cut, soft sheet-asbestos filled the opening less conspicuously than felt.

The spandrel walls were reinforced throughout their middle-thirds, in order to render the formation of cracks at that point less likely.

In one case, this was unsuccessful, as one of the joints at the main bascule pier (Pier IV), with an unusually large sliding surface, failed to work, and a crack resulted in the spandrel wall at about the quarter-point.

Architectural Treatment.

Largely due to the far-sightedness of the Hon. Brand Whitlock, then Mayor of Toledo, in securing the appointment of a consulting architect of broad experience in public work to co-operate in the beautification of the design, the Cherry Street Bridge when completed on this plan will be one of the notable structures in the United States. With the strong and graceful outlines of the engineer's design, and with little in the way of applied ornament, the treatment brings out the natural beauties of the structure by a judicious use of the shade effects of paneling and moulding. The attention of the observer is naturally directed to the lift-span, which, when closed, forms an arch almost twice the length of the adjacent ones, and when open, is the most striking object in the harbor. Realizing this, it is made the central feature of the design, and four tall columns, or towers (Fig. 5), rising from the two massive bascule piers, direct attention to it. Without these, the open position, with erect leaves breaking the sweep of the arches, gives an appearance of awkwardness—a utilitarian distortion of the structure. By the use of the towers, which dominate the leaves, and the massive piers, the effect of a gateway to the city is secured, and the passing of one of the mammoth lake freighters through the bridge (Fig. 6) will be the climax in its beauty.

The details of the tower and bascule pier design are shown by the architect's model, Fig. 7. The towers (unless the present City Administration sees fit to change the plans), will rise 150 ft. above the water and be topped by powerful lamps. The bases of two serve as operators' rooms and those of the others as public comfort stations. The hand-rail is very massive, not pierced except over the bascule piers, and is broken by panels and offsets at the piers and at regular intervals between. The pier noses are half round, up to Elevation 106, above which point, the pier is flat, set out from the wall 1 ft. 4 in., and marked with horizontal rustications. (See Fig. 8.)

The surface treatment of the bridge consists of roughening certain portions, exposing the special aggregate of small gray and yellow limestone chips which was cast against the forms, and, for contrast,

leaving untreated or smooth-rubbed, the bands and mouldings. The lighting system first contemplated consisted of a line of metal columns at close intervals along each hand-rail. Each column was to carry a single large globe containing a cluster of lights. Further consideration of the probable cost of lighting the structure under this plan forced a change. The system adopted has somewhat similar columns, but, with less powerful lights, and at longer intervals, along the curb.

Construction.

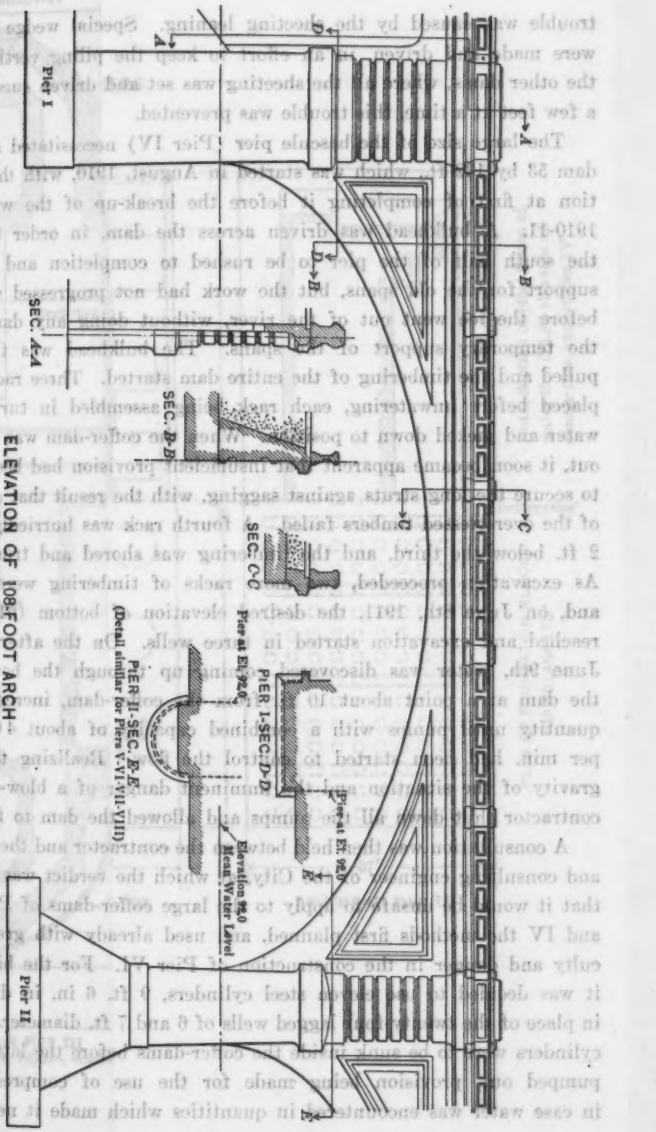
As might have been expected, the construction was very much complicated and lengthened by the necessity of maintaining traffic on the old bridge during the building of the new one. Although the superstructure had to be constructed in halves, it was first planned to build all the piers their full length and, where necessary, to carry the old bridge on temporary trusses and girders across the coffer-dams. According to the original plan for foundations, provided in the design, cylinders were to be put down to rock by the "Chicago" method, by first pumping out the coffer-dams and then digging the wells in the open, lagging them with tongued and grooved staves held in place by iron bands, as the excavation proceeded.

This daring and unusual procedure in work of this nature would have involved unwatering single-wall coffer-dams up to 53 by 152 ft. in size against a head of 30 ft. of water, and then starting from the bottom thus exposed and digging from 12 to 24 wells as much as 45 ft. farther, to rock. The work would have been through a blue clay, shown by the borings to contain pockets and streaks of sand.

Work was begun under this plan on Pier VI, on August 9th, 1910. A single-wall coffer-dam, 24 by 90 ft., of steel sheet-piling 46 ft. in length, was driven around the pier site. For that part of the dam under the old bridge, the sheeting was assembled complete for each side and floated in, suspended in a vertical position from staging built on a barge. To drive it, a heavy forging was hung from the top of the pile, which allowed the hammer to work several feet below the pile top. The timbering was placed as the dam was unwatered, and was very heavy, consisting of seven racks, 4 ft. 3 in. apart vertically. The contractor's full pumping equipment not having arrived, there was considerable difficulty in getting the water "started down" in this dam. Three sand dredges, equipped with two 8-in. and one 10-in.

centrifugal pumps, were finally pressed into service to aid the 8-in., steam-driven centrifugal and two reciprocating pumps of the contractor's plant. As soon as a difference of head was secured, a mixture of manure and ashes, dropped along the dam on the outside, successfully stopped the leaks. Grouting through holes in the sheeting was also resorted to where the leaks occurred below the level of the river bed on the outside. After the excavation and timbering were completed, the twelve wells were started in the bottom of the coffer-dam and successfully sunk to rock, the work being done in a constant shower of water in many cases and despite the hazards of the method, which were fully realized by the contractor's men. Continual pumping was required in several of the holes, and emphasized the danger of a blow-out. At one time, it seemed as though it would be necessary to excavate a couple of the wells through water, have a diver clean off the rock, and then deposit concrete under water. The leakage was finally controlled by grouting through pipes driven down alongside the cylinders on the outside and through holes drilled through the lagging. As soon as they were completed, the wells were concreted to a point 1 ft. above the bottom of the pier excavation. Six 60-lb. rails were placed in the upper portion of the cylinder as reinforcement. The pier shaft was carried up in successive lifts to the under side of each rack of timbering. After waiting 48 hours in each case, the dam was braced against the concrete, the rack removed, and the concreting continued. In subsequent dams, where much less timbering was used, the struts were concreted into the pier to within 10 ft. of normal water level, Elevation 92, and were afterward cut off flush with the face of the pier.

At about the same time, work was begun on Piers IV and IX, at both of which temporary supports had to be provided for the old spans, to allow the piers to be removed. At Pier IX two plate-girder spans, and at Pier IV four timber Howe trusses, were utilized to support the spans over the center of the coffer-dams. Great difficulty was experienced in driving the dam at Pier IX, the steel piling being deflected, buckled, and opened by the obstacles encountered. Work on this pier, though begun at this early date, was not finished until May 9th, 1912. Ultimately, an outer wall of Wakefield sheeting had to be driven around the worst portion of the dam. Under the bridge, where it was necessary to drive the sheeting down through the floor, one pile at a time,



ELEVATION OF 108-FOOT ARCH
PIER I TO PIER II
FIG. 8.

PIER II-SEC. E-E
(Detail similar for Piers V-VI-VII-VIII)

trouble was caused by the sheeting leaning. Special wedge sections were made and driven, in an effort to keep the piling vertical. In the other dams, where all the sheeting was set and driven successively a few feet at a time, this trouble was prevented.

The large size of the bascule pier (Pier IV) necessitated a coffer-dam 53 by 132 ft., which was started in August, 1910, with the intention at first of completing it before the break-up of the winter of 1910-11. A bulkhead was driven across the dam, in order to allow the south half of the pier to be rushed to completion and furnish support for the old spans, but the work had not progressed very far before the ice went out of the river, without doing any damage to the temporary support of the spans. The bulkhead was therefore pulled and the timbering of the entire dam started. Three racks were placed before unwatering, each rack being assembled in turn above water and jacked down to position. When the coffer-dam was pumped out, it soon became apparent that insufficient provision had been made to secure the long struts against sagging, with the result that a couple of the overstressed timbers failed. A fourth rack was hurriedly placed 2 ft. below the third, and the timbering was shored and trussed up. As excavation proceeded, two more racks of timbering were placed and, on June 8th, 1911, the desired elevation of bottom (61.0) was reached and excavation started in three wells. On the afternoon of June 9th, water was discovered coming up through the bottom of the dam at a point about 10 ft. from the coffer-dam, increasing in quantity until pumps with a combined capacity of about 4 000 gal. per min. had been started to control the flow. Realizing then the gravity of the situation and the imminent danger of a blow-out, the contractor shut down all the pumps and allowed the dam to flood.

A consultation was then held between the contractor and the officials and consulting engineer of the City, at which the verdict was reached that it would be unsafe to apply to the large coffer-dams of Piers III and IV the methods first planned, and used already with great difficulty and danger in the construction of Pier VI. For the big piers, it was decided to use eleven steel cylinders, 9 ft. 6 in. in diameter, in place of the twenty-four lagged wells of 6 and 7 ft. diameter. These cylinders were to be sunk inside the coffer-dams before the latter were pumped out, provision being made for the use of compressed air in case water was encountered in quantities which made it necessary.

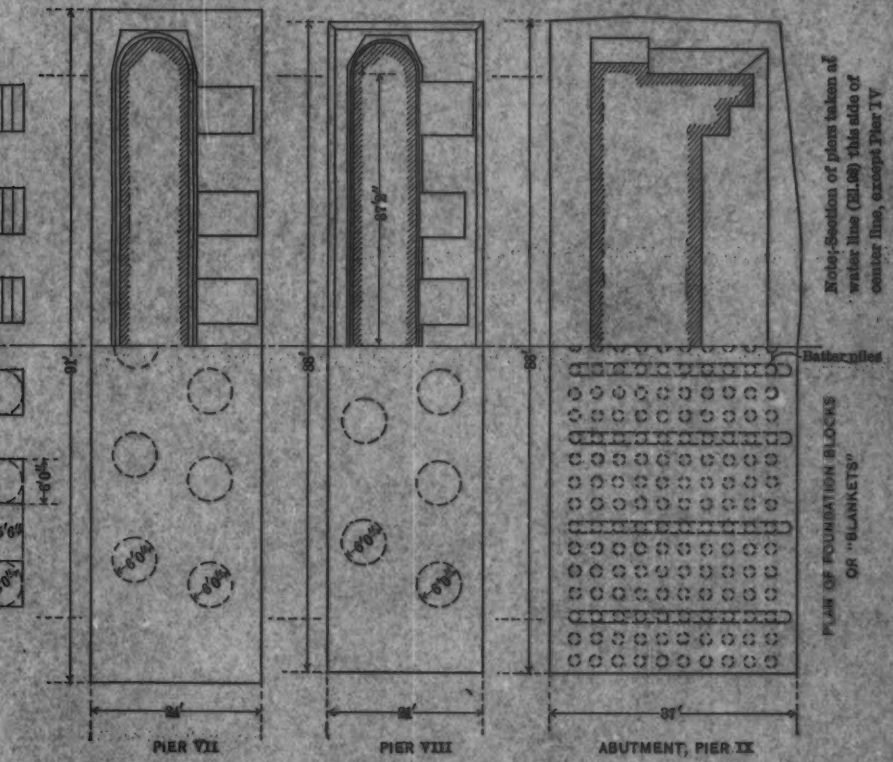
STRUCTURE DIAGRAM, SHOWING PLAN OF PIERS
CHERRY STREET BRIDGE
TOLEDO, OHIO



Below the elevation at which the cylinders were to be stopped the wells were to be carried down to rock with timber lagging, as in the original plan. After rock had been reached, the cylinders were to be filled with concrete up to the elevation of the base of the pier, and then the section of steel cylinder from there to the water's surface was to be removed. A layer or "blanket" of concrete, 10 ft. thick, was then to be placed over the entire area of the coffer-dam, being deposited under water by suitable means. The dam would then be timbered, pumped, and the pier shaft completed. Piers V, VII, and VIII were to be founded according to the original design, but, in order to expedite the work and prevent accidents, steel cylinders were substituted for lagging. To offset the increased cost of the foundations, piles were substituted for cylinders under Piers I, II, and IX, Pier II having little unbalanced thrust and the abutment piers affording an opportunity for a large spread of footing and massive piers.

The steel cylinders for Pier IV, as called for under these plans (Fig. 9), had a cutting-edge section 24 ft. 9 in. in length, to which could be bolted additional sections 6 ft. in length. A shelf around the inside of the bottom section near the cutting-edge supported the lining of concrete, 1 ft. 3 in. in thickness, which furnished part of the weight required for sinking. A wooden bulkhead was placed in the cylinders to float them while the lining was being placed, and was removed after the weight of the concrete had caused the cutting-edge to seal itself in the clay. As the cylinder followed the excavation down, additional top sections 6 ft. in length were added as needed. The third or fourth 6-ft. section added was a reducing section, decreasing the diameter from 9 ft. 6 in. to 6 ft., and allowed the placing of concrete weight blocks around the 6-ft. cylinder to get the needed sinking weight. The blue clay was cut with spades and removed in small tilting buckets. One stiff-leg derrick, mounted alongside the coffer-dam on piles, served all the holes except those under the bridge. The spoil from these latter was hoisted by runner lines working through snatch-blocks hung from the Howe trusses.

At Elevation 43.5 the material changed to a very hard dry clay or hardpan, which it was necessary to break up with a mattox or split off with bars and wedges. Limestone boulders, of all sizes up to ½ cu. yd., were encountered in this stratum, with occasional sand pockets, only a few of which showed any traces of water. The holes in most

cases were dry, trouble being usually caused by water following down alongside the cylinder after a sudden drop. At first, the steel cylinders were sunk to their limit before continuing them down to rock with wooden lagging. Later, after a Court decision that only the 24 ft. 9-in. section should be paid for, weight was taken off the cylinders as soon as all but a foot or so of this section was embedded in the clay. In continuing the wells below the cutting-edge, the shaft was excavated for distances of from 2 to 5 ft., and the hole was then lagged with short sections of double-grooved yellow pine sheeting, with radial edges and oak tongues. Steel hoops, 9 ft. 6 in. in diameter, made in three sections which bolted together, braced the lagging in place. In the last few feet to the bottom, where the material was favorable, the walls were often left unlagged. Bed-rock was found at elevations varying from 13.7 to 18.2 at this pier, and was usually a polished, flat limestone. The eleven cylinders of Pier IV were sunk a total distance of 490 ft. from July 28th to November 15th, 1911, with an average of 23½ days to each cylinder. The average daily progress, when work was not unduly delayed, was 2.7 ft.

During the next season, in putting down the wells for Pier III, several changes in the method of prosecuting the work resulted in shortening the time materially. An average interval of 17½ days elapsed on this side of the channel for the excavation of each cylinder, the work going forward at the rate of 3.1 ft. for each of the 15½ actual working days. In the first place, the sheeting was driven on only three sides of the dam, so that the cylinders could be concreted until nearly aground and then floated into position, instead of being lifted over the dam as before. The thickness of the shell of concrete was increased to 2 ft., leaving a shaft of 5 ft. 5 in., and making less additional sinking weight necessary in the shape of concrete blocks. Two derricks were provided for hoisting the spoil. Gangs of three men in each hole worked in three shifts of 8 hours each.

Concrete for the cylinders was mixed on the floating plant and chuted to a hopper, from which it was dropped from 35 to 78 ft. through a 10-in. pipe to place. Observation of the concrete in the cylinders, during stoppages in the work, showed practically no separation of materials and a very marked packing and tamping of the concrete. Water at times accumulated in leaky holes, or from over-wet batches, to such an extent that drying the mix did not take it up, and

bailing had to be resorted to. After concreting to the proper elevation in the shafts, the top sections of the cylinder were lifted off and re-used.

When the coffer-dams for Piers V and VII were laid out, it became apparent that the grillages of the old piers would interfere with the construction of the new ones for their entire length, and the contractor accordingly proposed to construct the remaining piers of the bridge, except the bascule pier (Pier III), in halves, to be suitably bonded together. This was to be done without change in contract price.

Provision was made, by grooves and projecting reinforcing rods, for bonding the second half of each pier to the first. One problem which had to be met in building the piers in halves, was that of continuing the coffer-dam after the old pier had been removed and construction of the second half of the bridge had been started. At one pier, a heavy timber bulkhead was placed from the side-wall of the dam to a groove in the side of the pier. In other cases, half a section of steel sheet-piling was concreted into the side of the pier, with provision for its removal later. In the abutment piers, a concrete bulkhead wall was built across the coffer-dam. These bulkheads permitted the pulling and re-use of most of the sheeting of the first half of the dam. The up-stream wall of the old dam was left in place to protect the bulkhead until the dam was to be extended to enclose the second half, when it was pulled, and the side-walls were continued.

Pier VII was the first in which the bottom of the coffer-dam was covered with a "blanket" of concrete before unwatering—the procedure intended at first only for the two large piers. Though Pier VIII had been successfully unwatered without this, it was thought best, as the additional cost was moderate, to place a layer of concrete under water in the remaining piers, rather than risk pumping out the dams without it, against a head of from 30 to 32 ft. For the small dams, the dimensions of which were about 25 by 48 ft., a layer 6 ft. thick was placed. This was of 1:3:5 concrete with two extra bags of cement per cubic yard of concrete in the lower part, over the tops of the cylinders, and one extra bag per cubic yard in finishing the blanket, to make up for possible loss of cement. Before starting to concrete, a diver cleaned off the tops of all the cylinder shafts, in order to insure full bearing.

The preferred method of depositing concrete under water was by tremie, chuting the concrete directly from the spout of the floating

mixer barge into the hopper of the tremie, which was handled by either the fixed or floating derricks.

Tremie work, though practiced for years, is far from being standardized, and as it is on the details of the construction and the handling of the tube that success depends, the methods used at Cherry Street may be of interest.

The tremie pipe consisted of flanged sections of 12-in., spiral, riveted pipe, which were bolted together to make up the various lengths required. The top section was short and was riveted to a pyramidal hopper of ¼-in., sheet steel, stiffened with angles and having a capacity of about 1 cu. yd. The edges of this hopper rested on a timber frame, suspended from the derrick by slings at the four corners. The discharge pipe from the floating mixer was self-supporting, and was simply held in place over the hopper by lines, in such a way that its weight did not have to be lifted when the tube was raised. A signalman, usually accompanied by the inspector, "rode" the hopper, and gave directions to the hoisting engineman.

Three things which must be most guarded against in tremie work, under conditions such as those at Toledo, are, first, the "plugging" of the pipe; second, the loss of the charge; and third, allowing the concrete to drop through water as it leaves the pipe. The first causes serious delay, disturbance of the concrete already placed, and danger to derrick and tremie from efforts to start the concrete flowing, and, usually, in the end, loss of the charge, thus making it necessary to refill the tremie. It can be avoided by using a quite wet mix, with small aggregate where possible, and by having the pipe hoisted enough to start the charge moving just as the hopper starts to fill, instead of after it is full. There does not seem to be any advantage in having a pipe larger than that used on this work, in fact, Mr. E. B. Van De Greyn* has recently stated that an 8-in. tremie was used successfully on the foundations for the City Waterway and Puyallup River Bridges, at Tacoma, Wash.

The second trouble causes serious washing of the last of the concrete in the pipe, for, as the column of concrete nears the bottom, the water rushes up through it to fill the tube. Also, refilling the tremie always causes more or less washing out of the cement. Loss of charge can only be avoided by good team work between the signalman and

* *Engineering Record*, August 15th, 1914, p. 188.

derrickman. The lowering of the pipe to stop the flow must be started in time, so that the pipe will be completely sealed, at least when the concrete has lowered in the tube to about the water level. The pipe should be lowered gently so as not to disturb the concrete already deposited. The regulation of this speed and the proper moment for giving the signals are matters requiring considerable practice on the part of the men. Matters are greatly complicated when the tremie is handled from a floating derrick, which lurches when the load is lifted and again when it is dropped. To reduce washing in filling the tremie, a cement sack, loosely filled with straw, will act as a plunger and force the water before it as the weight of the concrete forces it through the tube. The sack will usually float to the surface after passing through the pipe.

The third trouble will cause loss of cement from the charge and churning of the deposited concrete. The pipe must be "picked", or lifted, just enough to start the flow, which will rarely bring the lower end out of the soft concrete previously deposited.

A concrete with a small aggregate is handled much more easily through a tremie than one with the larger sized stone used in open-air mass work.

In the small dams, the entire layer of 6 ft. was carried across at once, but, in Piers III and IV, two lifts of 5 ft. each were made, and the reinforcement was placed between. For that part of the blanket of Pier IV under the old span, a bottom-dump bucket was used, which was "telegraphed" (fleeted or drifted) in under from the fixed derrick to a line hung from the old bridge floor. It is a point much debated, in work with a bucket, whether a top cover protects the concrete from wash, or causes more wash by creating a partial vacuum as the charge empties. At Cherry Street, two canvas flaps, weighted on the edge, covered the surface of the concrete as the bucket was submerged. Observation of the blankets after unwatering the dams showed the expected layer of laitance and silt, from ½ in. to 2 in. thick, in the low spots of the surface, and a decided unevenness of the top surface, in spite of the care taken to get it as level as possible. Concrete under water (due to being in a denser medium) stands in slopes much steeper than would be possible with that laid in air. Samples taken from the blankets, after cleaning the surface, showed that an excellent, dense concrete had been secured. Of under-water concrete

9 000 cu. yd. were required for all the piers, of which 7 050 cu. yd. had been placed at the end of the 1912 season.

The floating mixer plant previously referred to is a type of equipment, used by several contractors along the Great Lakes, utilizing the now familiar method of tower distribution, as developed for land work. (See Figs. 10 and 11.) This means of putting concrete into place has several advantages over the floating derrick and bucket. There is less danger of damage to the forms by knocking out braces or breaking wiring, the men do not have to keep out of the way of rapidly moving buckets, and the speed is practically limited only by the capacity of the mixer. For work in pier forms, a rate of 350 batches per 9-hour shift was commonly maintained. For shorter periods, speeds up to 50 batches per hour were made, but the total for the shift was usually cut down by the minor break-downs of material-handling machinery and delays incident to the shifting of sand and stone scows. The plant consisted of boilers, a hoisting engine, a stiff-leg derrick for hoisting material to the hopper bins, a ¾-cu. yd. Koehring mixer, and the elevator tower, all mounted on a barge 32 ft. wide and 100 ft. long. The tower was 56 ft. high, with the discharge hopper mounted on a slide, so that the chute could be raised or lowered readily, without changing its slope.

For Piers I, II, and IX, as previously mentioned, piling had been substituted for the concrete cylinders. The procedure in building these piers was much the same. After excavating inside the coffer-dam to a stiff blue clay, a test pile was driven, which showed the probable penetration that would be secured. Piling was then ordered of a length to give this penetration and extend a couple of feet above the bottom. In driving, a pipe of heavy 20-in. tubing was set in the leads, with its lower end on the bottom. The piles, which were usually shorter in length than the depth of the water, were dropped into this tube and driven with a follower to the desired penetration, by a No. 1 Vulcan steam hammer. About 25% of the piles in the two abutment piers had a batter of 2 in 12 and, for these, long piles were driven with batter leads and later cut off by a diver, or cut off above the blanket after pumping.

During the work on Pier II, an accident occurred in which loss of life was narrowly averted, and gave a remarkable proof of the abuse steel sheeting will stand. Before driving the piles, the channel had

been dredged with a floating dipper-dredge to blue clay, at a depth of 30.4 ft., and then a 30 by 60-ft. coffer-dam was driven. The piling was of the fabricated channel and Z-bar type used by the contractor throughout the work, and was driven to an average penetration of 10 ft. in the blue clay. After completing the driving of the bearing piles, the blanket of concrete, 6 ft. in thickness, was deposited under water, as in the other piers, leaving a 24.5-ft. head of clear water to be pumped against. The timbering was built up in place and sunk to position, and the final wedging was done as the racks were unwatered. The dam proved to be tight, and all the leaks were readily stopped with the mixture of oak sawdust, manure, and ashes. It was found that more discharge had been provided than was needed, and some of the pumps were cut out. At 11 P. M. on June 28th, 1912, the water was down 18 ft.; 5 min. later, just after the pump men had left the hole for their lunch, the timbering suddenly gave way. Though unwitnessed, it seems most probable that the accident was caused by the jar and weight of the pumps forcing the transverse timbers from their bearings on the walings.

At first sight, the wreck (Figs. 12 and 13) seemed to be complete, but as this pier was now one of the critical points in the completion of the bridge at the promised date, it was decided to make an attempt to straighten the dam, re-timber, and pump. This hardly seemed feasible at first, as the interlock was expected to be sprung so much by the bending of the sheeting over the edge of the footing-block that the leakage would be impossible to control. Examination of the dam above water, and by a diver below, showed that, following the collapse of the bracing, the sheeting had been sharply bent at an angle of 40° over the concrete. From July 1st to July 12th, the gangs were engaged in pulling the walls back to line at the water's surface and sinking a second set of timbering, after removing the wreckage. On July 13th, pumping was started, and, to the surprise of all concerned, the water was lowered so fast that some of the pumps had to be shut down in order to allow the carpenters time to wedge up the racks as they were unwatered. By July 15th, the water was down, and the leakage was easily controlled by a single 6-in. Cameron pump.

Examination showed that the sheeting had withstood its severe punishment without damaging the interlock at any point, and was holding tight, though bent in what would have been thought to be

impossibly sharp curves. Forms were rapidly built, and the pier was completed to the water line by July 19th.

Throughout this job, the contractor used about 40 000 ft. of steel sheet-piling of this type, in nine coffer-dams of an aggregate area of 21 300 sq. ft. It was easily driven and pulled, though there was considerable difficulty at times in starting to pull the piling where the footing-block had been cast under water directly against the riveted sheeting. All of it was used at least twice, and much of it oftener than that, on this first half of the job. The dams were unwatered in all cases with very little difficulty, against heads of clear water of from 20 to 25 ft.

The first work above water was started in May, 1912, when the piers on the east side of the channel had all been raised to Elevation 92, and the placing of the arch centers was begun. The contractor's scheme for the construction of the arch ribs was to cast them in successive parallel strips of about 12 ft. each, supporting the forms on steel centering until the concrete had attained its strength, and then shifting the centers sideways to cast the adjacent section. This plan was followed, with some variations caused by the necessity of rushing work on the approach of cold weather at the end of the season.

The contractor used five three-hinged steel arches, of span lengths to fit the openings on the east side, for the arch centering. For the two 108-ft. arches on the west side, later, the 108-ft. and 100-ft. centers were brought across from the other side of the channel, and the shorter one was lengthened out by bolting on members at the crown. Each center consisted of two three-hinged arch trusses, with a temporary tie to take the thrust during erection. In service, the thrust from the concrete load is carried into the piers through large bent plates at the lower hinges, the plates also serving as forms for that part of the pier. (See Fig. 14.) Fig. 16 shows the details of the centering, with the lowering wedges and rollers. The centers were supported on I-beams which crossed the piers at the water line in slots left for that purpose. These were concreted into the work, and were to be cut off later back of the face of the pier. These I-beams carried the longitudinal beams on which the rollers traveled in shifting the centers laterally. Fig. 17 shows the details of the forms for the arch ring. To secure the proper curve of the arch intrados, the outlines of semi-arches were first laid out on a large wooden platform in the

yard, and then a section of arch center was placed on its side in the correct relative position and templates made, from which the 6 by 12-in. joists were cut to the proper curve by a band-saw in the shop.

When planning the programme for pouring the arch rings, it was seen that the use of the arched centers introduced a problem not common to the ordinary timber falsework. This was the unbalanced thrust which would come on any pier from a partly or entirely completed arch on one side only. It was decided to start with the smallest arch at the east end and carry the concrete out only one-third of the distance to the crown at each pier in succession from there to the channel. This was done, the concrete fleet being shifted from side to side of the arch, so as to place fresh concrete on each surface not later than 2 hours after leaving it. As three surfaces had to be kept fresh, this moving took time and caused some risk of having a surface set before getting back to it. This, in fact, occurred at one of the points, and the rapidly hardening concrete had to be removed to form a surface normal to the thrust before the concreting could be continued. After pouring the lower part of the arches in this way, the crowns were finished as soon as the first concrete had set enough to permit the removal of the bulkheads. The floating mixer and tower handled this work very satisfactorily, as the batches could be chuted to down-spouts placed where needed through the top lagging of the forms.

After completing the first 12-ft. section, it was realized that if the plan of casting the arch ring in 12-ft. sections was adhered to, the work on the first half of the bridge could not be completed that season. It was then decided that it would be possible to cast the remaining width of 23 ft. of the half-arch barrel at one time, by increasing the load on the centers somewhat and dividing the remainder of the load between the Melan rib reinforcement and the section of arch previously completed. How this was accomplished is shown in Figs. 15 and 17. The transverse beams carried by the steel centers were prolonged with 12 by 12-in. timbers, notched to fit over the beams at one end and supported at the other end by bolts from the old concrete and in the center by stirrups which threw part of the load on the latticed ribs. As it would take more time to concrete this increased width of arch ring, the order of pouring was changed, with the idea of reducing the number of surfaces to be kept fresh. In order to do this, each

pier was poured separately up to the bulkheads at the springing line. This also embedded the ends of the latticed ribs and made them ready to act as arches in carrying their proportion of the load, later. As soon as the piers had set enough to resist the thrust of the arch centers, the haunches of the arches were poured to a point 15 or 20 ft. from the crown, the top lagging being in place before concreting was started. At this point, where the slope was about 2 in 12, the top lagging was stopped. While pouring the haunches, the crowns of the arches were loaded with concrete blocks, and, later, when pouring the crowns, the adjacent uncompleted arches were similarly loaded.

When concreting, one man worked between each pair of latticed ribs, puddling with his feet, or using a long 2 by 4-in. pole to reach the far edge of the concrete against the top lagging. Particular care was taken in this way to avoid the formation of rock pockets. The concrete came into the forms through hoppers placed at regular intervals along the top lagging. The plant was shifted from side to side of the arch at intervals of about 2 hours, so that fresh concrete was placed on the old before it had set more than 2½ hours. At this age, in the weather during which most of the work was done, the surface of the concrete was still soft enough to insure a good bond.

One of the chief difficulties encountered in the building of the spandrel walls, after the arch rings were complete, was the placing of the facing concrete which was used in order to secure an attractive texture of the concrete surface after bush-hammering. This mixture was of blue-gray and white limestone chips with a mortar of stone screenings and sand. Facing "irons" were first attempted, but were not feasible on account of the wet mixtures in use and a tendency to leave voids or rock pockets in the face of the work. The final method adopted was to use a liberal quantity of the mixture and pour it from buckets against the forms, keeping its level always slightly higher than the surface of the concrete. The rock pockets on the face that resulted from the attempt to use facing irons were filled later by use of the cement gun.

The arches were not ready for water-proofing until very late in the season, for the best results. The five-ply water-proofing over the arch barrels and inside of the spandrel wall, however, was placed as rapidly as possible after the completion of the concrete, so that the back-filling might be commenced. The order of work was to clean

FORMS FOR ARCHES AND DETAILS SHOWING MANNER OF SUPPORTING EXTRA WIDTH OF ARCH

Fig. 17.

the concrete surface thoroughly and then mop it with pitch. A three-ply layer of felt was then built up, and over it a final course of two-ply was placed. A layer of pitch was mopped on between all felt, and a final heavy coating was applied to the completed membrane. Over the expansion joints in the wall, the felt was laid up over a stick, which, when pulled, left a fold in the water-proofing, reinforced by two strips of canvas.

For back-filling, sand and gravel were dredged from the river, just below the bridge, by floating derricks, and dropped from the clam-shell buckets directly into place. The load was placed first mainly over the haunches along the entire series of arches, so that too much unbalanced load would not be thrown on the piers; it was then leveled off and shoveled to place by hand. Only material that would drain rapidly and easily was used.

Bascule Span.

The erection of the half leaves of the bascule steel was started in the fall of 1912, as soon as the back-fill had been placed so that the erection derricks could be set up. The steel was unloaded from a siding near the river and transferred to barges. The main girders were delivered in three sections, the largest of which weighed 36 tons. To handle these, the contractor used two of his standard steel derricks, with heavy cast-steel mast head, mast seat, and one-piece gooseneck. One derrick was elevated on bents and partly supported by the top chords of the old bridge, in which position it could place the top section of the girders. (See Fig. 18.) The other derrick was set directly on the spandrel filling, and was only used for the first heavy lifts. It was then dismantled and transferred to the other side, where it handled the large sections alone. (See Fig. 19.) Later, on that side, the boom was spliced out to 110 ft. to handle the top section of the girder and floor system.

Cold weather, high winds, and sleet and ice storms made the erection in winter very difficult, but it was pushed, in order to be sure of having the half width of the bridge ready for use at the break-up of the winter of 1912-13. (See Fig. 20.)

On the original designs for this bridge it had been determined that the movable span was to be a double-leaf bascule, supported by four lines of cantilever girders the lower flanges of which curved to

balance the dead load of each girder, 387 tons of concrete counterweight is provided, as shown by Plate XXIX and Fig. 23. The live-load uplift at the rear end of each girder is transferred to four round steel rods extending to an anchorage in the masonry of the pier. Details of the bascule floor are shown on Plate XXXII.

A 75-h.p., railway-type motor is mounted between each pair of girders to operate the structure. From this motor, a train of gears reduces the speed from 560 to 1.1 rev. per min. at the drive pinion. Each leaf can be operated from its own side of the channel, or both can be worked together by the operator in the main control house, the successive positions of both leaves being indicated there by signals.

Completion of the Work.

This account carries the history of the bridge up to the spring of 1913, at which time the writer's connection with the work ceased. The construction work in the season of 1913 was practically in all details a duplication of that done previously, after the removal of the old steel spans permitted building the second half of the structure. With the old bridge out of the way, and profiting by the experience of the preceding years of work and with an organization trained to the methods in use, far better time was made in this working season. Except that both halves of Piers III, IV, and VI, were complete at the beginning of the season, practically the same amount of work was done between March and December 31st, 1913, as in the preceding 2½ years. To avoid the loss of time incident to casting the arch rings in parallel sections, an adaptation of the method followed during the preceding year, to increase the width of strip cast, was used, together with some pile falsework, to permit of casting the entire remaining width of the arch ring at one time. Erection of the bascule was started before the end of the year, and by January 1st, 1914, the work of the contractor for the concrete construction was practically done and most of the bascule steel was in place. The fact that the channel was closed by ice allowed the erection sub-contractor to place the girders for the second half of the span in their horizontal position and connect them to the first half leaf while it remained closed.

Quantities and Cost.

The unit prices bid by the C. H. Fath and Son Construction Company, on March 3d, 1910, for this work were as follows:

Removing old masonry from piers and old rip-rap from ice-breakers and around old piers, per cubic yard	$1.50
Removing timber grillage from under old piers, per 1 000 ft. b. m.	15.00
Pulling old piles, each	3.00
Excavation and removal of sand, earth, and gravel inside coffer-dams and above cylinder piers, per cubic yard	1.50
Clay in coffer-dams or in cylinders, per cubic yard	1.65
Hardpan in cylinders, per cubic yard	1.80
Rock in cylinders, per cubic yard	3.50
Steel rings in cylinder shafts (not removed*), per pound	0.07
Steel rings in cylinder shafts (removed*), per pound	0.04
Timber lagging for cylinder shafts, in place, per 1 000 ft. b. m.	70.00
Old rails for reinforcing piers, abutments and cylinders, per long ton	30.00
Class "AA" concrete, for slabs, beams, girders, columns, etc. 1:2:4 mix	$10.80 per cu. yd.
Class "A" concrete, for arch rings. 1:2:4 mix	19.00 " " "
Class "B" concrete, for spandrel walls, etc. 1:3:6 mix	10.80 " " "

(In construction this was actually changed to a 1:2:4 mix, using small stone instead of the 2½-in. limit specified.)

Class "C" concrete for piers above mean water level. 1:3½:7 mix	$7.35 per cu. yd.
Class "D" concrete for mass work in piers below mean water level (with embedded stone permitted up to 33%) 1:3½:7 mix	6.00 " " "
For the same, in cylinders	5.25 " " "

* * *

* Provision was made for using metal lining for the cylinders, if necessary, at a price of 7 cents per lb. if left in place. When the method of foundation was changed, this price was applied to the steel cylinders, with a deduction of 4 cents per lb. for steel removed.

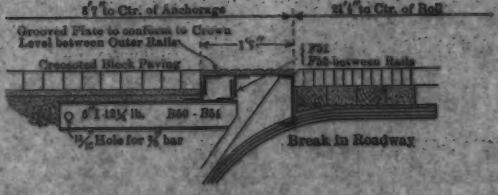
Post every Panel Point

Intermediate Post every Half Panel.
" " near Pier Points.

The location of these pieces to be determined by rails.



To January 1st, 1914, the amount expended for various items in the construction of this bridge was as follows:

Maintenance of old bridge and removal of old masonry, etc.		$42 196.80
Construction and maintenance of the nine coffer-dams, lump sum		181 500.00
Excavation, under four classifications (with 75 cu. yd. of rock)	31 625 cu. yd.	49 075.05
Timber piling, in place	35 779 lin. ft.	14 311.60
Steel and wood lagging for foundation cylinders		103 595.82
Mass concrete in cylinders, piers, etc., in three classifications	19 795 cu. yd.	119 596.05
Concrete in arch rings, 1:2:4 mix	8 916.6 cu. yd.	177 440.34
Concrete in spandrel wall, pier faces, and viaduct, in three classifications	7 519 cu. yd.	88 705.00
Concrete in foundation blankets, placed under water, including cost of extra cement	9 420.0 cu.yd.	63 024.30
Concrete parapet wall, total lump sum = $10 000		7 800.00
Finishing surface of bridge, total lump sum = $6 000		3 000.00
Steel reinforcement	732 tons	54 210.00
Water-proofing arches and spandrel walls, lump sum		20 000.00
Spandrel filling	11 800 cu. yd.	9 440.00
Setting bascule anchorage	197.5 tons	5 925.00
Miscellaneous items		3 785.00
		$943 605.16
Contract cost of bascule		132 980.00
		$1 076 585.16
All other expenses, May, 1906, to January 1st, 1914		89 082.23
Total cost to January 1st, 1914		$1 165 667.39

These items may be roughly summarized as follows:

Substructure work, new	$518 000	
Removal of old bridge masonry, etc.	32 000	
		$550 000
Concrete superstructure	$380 000	
Steel bascule span	138 000	
		518 000
Miscellaneous expense		98 000
		$1 166 000

It has been estimated by those in charge of the work since January, 1914, that the cost to complete all unfinished work after that date, exclusive of the towers (the fate of which at present hangs in the balance) would be about $15 000, besides claims not yet adjusted amounting to about $40 000.

The original design of the Cherry Street Bridge was made by the Osborn Engineering Company, of Cleveland, Ohio, under the direction of Wilbur J. Watson, M. Am. Soc. C. E., at that time the Bridge Engineer of that Company.

In July, 1910, Ralph Modjeski, M. Am. Soc. C. E., was appointed Consulting Engineer in Charge. No changes were made by him in the general features of the design, with the exception of those involved in the methods of securing the foundations, already described, certain revisions in the proportions of the arch rings and the design of the reinforced concrete viaduct, and those changes incident to the use of the Scherzer instead of the trunnion bascule. All construction work was done under his supervision. In April, 1911, Mr. Arnold W. Brunner was retained by the City as Consulting Architect, and the external treatment of the structure was handled by him, in conjunction with Mr. Modjeski.

Gustavus A. Gessner, M. Am. Soc. C. E., was Resident Engineer from the commencement of work until December, 1911, and W. R. Weidman, M. Am. Soc. C. E., from that date until January, 1914. Mr. M. B. Case and the writer were Mr. Weidman's Assistants during the year and a half preceding June, 1913. The main contract, except for the bascule span, was in the hands of the C. H. Fath and Son Con-

struction Company, until the season of 1913, when the National Foundation and Engineering Company was organized to complete the work. Mr. M. J. Comer was Superintendent. The contract for the Scherzer span was assigned to the Toledo Bridge and Crane Company, and the steel was erected by the Kettler-Elliott Erection Company.

DISCUSSION

Mr. Godfrey.

EDWARD GODFREY,* M. AM. SOC. C. E. (by letter).—This paper is another exemplification of the fact that engineers are capable of taking up and solving the big problems of construction, and for this reason it is a very valuable addition to engineering literature.

The paper also illustrates the fact that some of the smaller problems, the so-called details of design, are not given the thought and attention that their importance deserves. Engineering science is not balanced in this respect. The big things are worked out to the exclusion of details that are of equal, and sometimes of greater, importance.

It was a small thing that caused the Quebec Bridge to fall, a mere detail, the entire absence of bracing in a great traveler 217 ft. high. A great deal of work and thought were devoted to the subject of secondary stresses, which in material of the toughness of steel is of little or no consequence; but the simple matter of preventing the lateral swaying of 1 000 000 lb. of steel, held more than 200 ft. in the air, was given no consideration whatever.

The writer checked a set of details for structural work of two theaters. There were twenty-two types of errors, some of them repeated many times: Cantilevers had little or no provision for bending at the section of greatest moment; some had provision for tension but none for compression; curved girders had nothing to prevent them from flopping down, as did a large one in the Orpheum Theatre, in New York City, pulling the entire structure with it. Other errors were found. This was the work of one who held himself to be a capable structural engineer.

With practically no exception, great structural failures (excluding dams) have been due to lack of bracing or lack of attention to details of design.

Fig. 3 shows that the columns of the approach viaduct of this bridge are of square and oblong shape, having upright rods and so-called hoops 12 in. apart. A rectangular hoop is the latest thing in "squaring the circle". The writer has publicly described and shown a photograph of a column of this kind that broke at 200 lb. per sq. in. due to the mere shock of a near-by wreck. These columns, by the writer's calculation, are loaded to 400 or 500 lb. per sq. in., and belong in the class that has characterized nearly all the many reinforced concrete wrecks, where the columns are broken up into short chunks or ground to a shapeless mass.

It is true that the Report of the Joint Committee allows columns of this sort, with only wires enough to hold the upright rods in place during the hardening of the concrete; it also allows plain concrete columns. If these columns were not more than 24 ft. high, and had

* Pittsburgh, Pa.

no steel whatever, they would satisfy that Report, but the writer would hate to live under the viaduct. Mr. Godfrey.

The columns of this viaduct were not even chamfered on the corners. T. L. Condron, M. Am. Soc. C. E., says of the rodded columns of the Edison Building:*

"In places where the heat was not sufficient to destroy the insulation on electric wires strung through the ceiling, square columns were spalled almost as badly as those in the rest of the building where the heat was exceedingly great."

These facts and the failure of the column at 200 lb. per sq. in. indicate clearly that there is an intensity of strain in such columns ready to break out in failure from small contributing causes. All know what happened to the columns of the Edison Building, and how so many of them failed, and how so large a portion of one of the buildings collapsed on account of such failure, and also that such columns have been roundly condemned.

The rods in the Edison Building were 3 in. from the surface, and yet many of them broke out and split the columns from top to bottom, both those at the corners of columns and those in the middle of the sides. They did not have ties, but it is unthinkable that a few square hoops could redeem such members and make them fit to sustain a structure. The column which failed at 200 lb. per sq. in. was oblong, and had regulation ties, such as the oblong columns of this viaduct. The concrete was good and well seasoned.

The time will come when engineers must realize that not everything stated in books and committee reports is safe to follow, and the so-called destructive critic must be reckoned with. The writer has been publicly condemning columns of this kind for ten years, and he has yet to hear any better argument in favor of them than this: "Mr. Godfrey's views are not in agreement with the majority of the Profession."

Circular or octagonal columns with upright rods (not for compression but for transverse strains) and close-spaced hooping constitute proper reinforced concrete.

Another criticism that the writer would make concerns the floor-beams of Fig. 3. The main reinforcing rods are bent up at 45 degrees. Some of them run to the support, and some stop short of it; but they are not anchored over the supports. The beams are cluttered with stirrups, the use of which no one has ever been able to explain. If these main reinforcing rods had been run up over the top of the support and then curved down for anchorage, or, in the case of the middle post, had extended well into the next girder for anchorage, the construction would be very greatly improved. In the case of a common support of two girders, there is a large tension in the top of the

* *Journal*, Am. Concrete Inst., July, 1915, p. 397.

Mr. Godfrey.

girder over the supports. The rods of one girder should be bent up and continued well into the other one, in order to take this tension and anchor those rods for the diagonal tension or shear. In this bridge, a number of long rods could have been left projecting out of one floor-beam to be built into the other when the latter is made. Steel disposed in this manner is of definite value, whereas the aimless stirrups commonly used are a hit-and-miss sort of makeshift.

The steel used in stirrups would be vastly more beneficial if it was converted into main reinforcing rods curved up and anchored over the supports. Tests and common sense demonstrate this. Besides increasing the strength and safety of structures, this would make them cheaper and simpler to build.

Another detail of design to which the writer would call attention is on Plate XXXII. The sidewalk cantilever has a pull at the top flange which the writer calculates to be about 19 000 lb. To take this pull there are two rivets in tension on their heads, as shown by Plate XXX. The angle to which the sidewalk bracket is attached is connected to the bascule girder by only two rivets, and the top chord of the bracket is pulling directly on their heads. Besides this, the connection is eccentric. This is a detail that is very commonly slighted, and illustrates what the writer stated at the beginning of this discussion. A detail worse than this one could scarcely be devised. It behooves the engineers of this bridge to see to the correction of it before the sidewalk drops into the river.

The writer is familiar with a long viaduct where the sidewalk brackets are dependent on tension on four rivet heads the severance of which would mean, not only the dropping of the sidewalk, but the wrecking of the supporting girder.

Mr. Ritchie.

JAMES RITCHIE,* M. AM. SOC. C. E. (by letter).—The writer is much interested in this paper as he was in charge of the work for the firm of contractors which built all except the steel bascule spans. Mr. Chase has described very fully the methods used in the construction of the first half of the bridge, and a few additional details from the point of view of the contractor may be of interest.

Referring to the historical sketch, there are a few additional facts which came under the writer's observation. The first estimate of cost made by the designing engineers was $515 000, and on this basis the City of Toledo issued bonds and secured a fund of $525 000 for the building of the bridge. In the summer of 1907 proposals were asked for, but only one was received, which was more than $900 000. The matter was then discussed, and various plans were suggested, but finally, in July, 1909, proposals were again asked for, and three bids were received on the plans of the City and three alternate bids

* Cleveland, Ohio.

on the bidders' own plans. One of these alternate bids was for $897 000, and was made by the same firm which had bid alone on the first advertisement. One of the other bids was based on a different form of reinforcement of the arches from that shown on the City's plan, and the other bid was on a totally different method of construction. The lowest bid on the City's plan amounted to about $813 000, and therefore would require at least $300 000 more than the City had in its fund for the work. Even the lowest of the alternate plans required more than the City had appropriated, and the question which plan to adopt was discussed for several months. Finally, it was submitted to a board of expert engineers, and they recommended the adoption of the City's plan. The necessary additional funds were secured, and on March 3d, 1910, the contract was awarded. Immediately thereafter the firm which had submitted the lowest bid on an alternate design brought suit, through a resident of Toledo, to enjoin the City and the contractor from carrying out the contract. Decision on the suit was rendered in favor of the City and the contractor, in the Court of Common Pleas, and the case was appealed to the Circuit Court, which sustained the lower Court. Pending the decision in the Circuit Court, and at the request of the City, the contractor started work on the construction during June, 1910. Mr. Ritchie.

Plans were made by the writer which contemplated removing the old bridge to a temporary site and supporting the spans on pile piers, so as to leave the site of the new bridge unobstructed, but this idea was abandoned, not so much from fear of the action of ice on temporary work as because the recent decision of the Court had affirmed the fact that the method contemplated by the City's plans of building the superstructure in two halves was practicable, and the City did not wish to raise the question again before the public.

The easterly bascule pier, known as Pier IV, was placed so that the existing pier, supporting the east end of the 300-ft. swing bridge and the west end of a 175-ft. fixed span, had to be wholly removed and its foundation piles withdrawn before the bascule pier could be constructed. The coffer-dam for the bascule had to be at least 48 ft. 6 in. wide to contain the base of this pier, and this width had to be increased to 53 ft. on account of the projecting base of the old pier, which was at the extreme edge of the coffer-dam. In order to support the old bridge at this point without interfering with the river traffic, as well as the traffic over the bridge, it was necessary to have supporting trusses with a clear span of 60 ft., to provide very heavy pile supports for them, and to construct the trusses so that the old bridge would be supported rigidly for the fixed span and on the end wedges for the swing span. The temporary trusses had to sustain the loads at the site of the old pier, and this point was about 15 ft.

Mr. Ritchie.

from the west support and 45 ft. from the east support of the temporary trusses.

The old piers were first cut out by vertical slots of the width necessary to receive the temporary trusses, leaving a stone column to support the ends of the trusses of the old bridge. The temporary trusses were then placed in position and, after they were ready, the stone column was cut out for a sufficient space in which to place a jack on each side of the end post to hold it, while enough stone was removed to permit the placing of the wooden beams which were to transfer the load to the temporary trusses. This latter work had to be performed during the night when the traffic could be interrupted, and this was only from midnight until 5 A. M.

Four timber trusses were used at the bascule span and four plate girders at the east abutment. The top and bottom chords of the Howe trusses were each made of two pieces of 12 by 16-in. Oregon fir, each piece being 84 ft. long, thus being the full length of the trusses over the supports and requiring no splices, and thereby requiring only enough falsework to keep the sag out of the timbers while putting in the web members. The plate girders at the east abutment were put in position by a floating derrick, and also required no falsework for their erection.

The old bridge had a total width of 42 ft., and, in order to construct the north half of the new bridge, it was necessary to remove the north sidewalk of the old bridge. It was also necessary to move the two end spans into line with the other spans. These were originally placed so that there was a bend in the roadway on the bridge. To make this change in the end spans, falsework was built at the south ends of the piers, and, when all was ready, the two spans were jacked over to their new position on a Sunday afternoon.

While the first half of the bridge was being constructed, the City awarded a contract for a new foundation of a bridge at Ash Street, about a mile north of Cherry Street, contemplating the use of the old Cherry Street spans for the superstructure of the Ash Street Bridge, and as soon as traffic was turned over the first half of the new Cherry Street Bridge, the old spans were taken down, new floor-beams ordered, necessary repairs made to the old parts, and the spans erected on the Ash Street piers. The old trusses were found to be in good condition, and, being of wrought iron, the members had not deteriorated in the 30 years of use, having been kept well painted during all that period.

Mr. Chase has well said that the removal of the old bridge and the experience gained by the company in constructing the first half, was the reason for the rapidity with which the second half was completed. The company regrets that the plan of removing the old bridge to a temporary site—suggested in the first place—was not carried

out, as experience has shown that the cost of such removal would have been infinitesimal compared with the expense incurred and the delays occasioned by having to construct the bridge in two parts. The company's records show that the whole bridge could have been completed by the time that the first half was ready for traffic, thus saving more than a year of overhead expense, to say nothing of such difficulties as the obstruction caused by the piers, the temporary supports, the building of two coffer-dams, instead of one, for six of the piers, and the maintenance of traffic over the old bridge. Mr. Ritchie.

CLEMENT E. CHASE,* JUN. AM. SOC. C. E. (by letter).—The writer believes that Mr. Godfrey's apprehensions concerning the safety of the columns in the viaduct approach of the Cherry Street Bridge would be somewhat allayed if he were to see the completed structure, and thus get a better idea of its proportions and loads. The columns are 13 and 16 ft. long in the 2-ft. square and the 2 by 3-ft. sections, the cross-section in the remainder of the height being very largely increased. They were of square and oblong sections in the original design by the Osborn Engineering Company, and these shapes were retained in the revised design, prepared by Mr. Modjeski, largely for the sake of appearance and economic construction. Circular columns, although excellently shaped as far as strength alone is concerned, would have required expensive form work in this case, particularly at the fascia girder, and would not have corresponded with the architectural lines of the rest of the structure. The columns were of 1:2:4 concrete, very carefully mixed, and well worked in placing, to eliminate voids. Mr. Chase.

There may be doubt whether rectangular ties restrain effectively the rods in the middle of the side of a rectangular column, if it is stressed in compression so heavily that both steel and concrete are needed to carry the loads, but there is no reason why the restraint of the corner rods, even in such a case, should not be just as effective as is that of circular ties on the rods in round columns. In the moderately compressed columns at Cherry Street, the reinforcement, disposed as it was, is certainly capable of taking care of the small bending stress and any probable shock.

Some of Mr. Godfrey's other criticisms of the detailing in this structure have served to call attention to points which are incompletely or inaccurately presented in the drawings. The main rods of the floor-beams were bent up at an angle of 45° at both ends, and were anchored at one end by a loop into the fascia girder. At the other end they were extended as far out of the half of the girder first constructed as the adjacent old span would permit, which was sufficient to give an ample bond with the second half of the bridge. Also, all corners of

* Pittsburgh, Pa.

Mr. Chase.

columns and beams were chamfered liberally. These points are not shown accurately in the drawings.

The vertical stirrups, to which exception is taken, were spaced so that the shear on the concrete would not exceed 60 lb. per sq. in. Failure by diagonal cracking is resisted effectively by vertical stirrups, even if their exact disposition may not be subject to rigid analysis.

In commenting on the sidewalk bracket connection to the bascule girders, Mr. Godfrey has drawn his conclusions from insufficient information. Details of this connection are not given in the paper. In addition to the two rivets in tension, which are shown in the girder view, Plate XXXII—which Mr. Godfrey guessed were all that held the bracket up—there are from five to six rivets in shear, connecting a top horizontal plate to the top flange of the grider. The maximum stress in the top chord of the cantilever bracket is only 15 000 lb.

Mr. Ritchie has added several facts of interest which supplement the writer's account of the operations of his company. The construction of the bridge in two longitudinal halves certainly added greatly to the cost and length of time required to construct the complete bridge. The Cherry Street Bridge was, as he intimates, a storm center in Toledo's political life from its inception until its completion, and hard-won legal victories could not be jeopardized by changes in the plans of construction which otherwise might have been made as their desirability developed.

Paper No. 1363

THE FAILURE AND RIGHTING OF A MILLION-BUSHEL GRAIN ELEVATOR*

By Alexander Allaire, M. Am. Soc. C. E.

With Discussion by Messrs. David Gutman, W. R. Phillips, and E. P. Goodrich.

Synopsis.

The object of this paper is to present to the attention of the members of the Society the history of a rather unusual engineering feat. The size of the building to be straightened, the angle to which it had tipped, and the weight to be handled, all combined to make the work unique.

The restoration of the elevator to a working condition may be divided into four parts:

1.—Making safe the foundations under the workhouse—a structure resembling a tall office building, resting on a very small base;

2.—Straightening the binhouse, a structure having an area of 15 000 sq. ft.;

3.—Providing this binhouse with a new and adequate foundation; and

4.—The renewal and repair of those portions of the original buildings which had been broken or deranged at the time of the failure.

This paper treats of the first three.

* Presented at the meeting of February 2d, 1916.

The Canadian Pacific Railway, which serves as the principal outlet from Western Canada, in 1911, found it imperative to provide relief for its Winnipeg Yards, which were yearly becoming less and less able to meet the demands on them. During October, November, and December, Canada's immense wheat-producing provinces of Manitoba, Saskatchewan, and Alberta ship their grain to the United States and Europe *via* the Canadian Pacific Railway to Fort William, where it is loaded on the Lake boats. To relieve the congestion, a cut-off was made, running approximately 3 miles north of Winnipeg, and one of the largest railroad gravity yards in the world was built at North Transcona, 7 miles northeast of the city. As an additional aid to the speedy shipment of the grain, a million-bushel elevator was constructed at the North Transcona Yard. This is to serve for storage during the "peak" periods, and relieve the car shortages by sending empties back West several days earlier than would be possible, should these cars have to go as far as Fort William.

The country in the vicinity of Winnipeg is flat, and the character of the soil is quite uniform throughout the district. First there is a stratum of about 2 ft. of heavy black loam, below which there is reddish gray clay, 5 or 6 ft. in thickness, and generally water-bearing, and this gradually changes to a blue clay extending to a depth of approximately 40 ft. below the surface, where it changes suddenly to white clay interspersed with limestone boulders. Underlying the white clay is found a stratum, averaging about 30 in. thick, of shattered limestone which in turn overlies the limestone rock. At Transcona this rock varied from 53 to 55 ft. below the prairie level.

Usually, the blue clay found at the depth from 7 to 8 ft. below the surface is very firm, and is capable of carrying a load of from 3 to 4 tons per sq. ft. As a result, it has been the practice in the Canadian Central West to use floating foundations. In building the elevator, therefore, this general custom was followed.

The ultimate loading of the clay under the mat was calculated at 3.3 tons per sq. ft. As a matter of precaution, soil-loading tests were made at different points on the site. From the result, it was thought that the customary slight initial settlement might be experienced, but that nothing more serious should occur.

The general layout consists of four units; a workhouse, 70 by 96 ft. and 180 ft. high; a binhouse, 77 by 195 ft. and 102 ft. high; a dryer-

house, 18 by 30 ft. and 60 ft. high; and a boiler-room equipped with two 100-h.p. locomotive boilers. The workhouse rests on a reinforced concrete floor, 30 in. thick, and is a reinforced concrete structure, with brick curtain-walls as the top is approached. The basement of the building is 16 ft. high. In it are the belts for transferring the grain from the cars to the conveyor-boots, and from the binhouse to the workhouse. The ground, or prairie-level, floor is occupied by the cleaning and drying machinery. Above these machines there are fifteen bins, 13 ft. in diameter and 70 ft. high, above which again are several floors carrying the weighing machines, etc. The floor, machinery, and wall loads above the second floor rest on twenty-four interior columns, placed in four rows of six columns each. The interior columns carry a load of about 800 tons each; the exterior ones carry about 500 tons each. Fig. 1 shows the workhouse in plan and elevation.

The binhouse, immediately north of the workhouse, consists of sixty-five circular bins arranged in five rows of thirteen each. These bins or tanks are 14 ft. 4 in. in diameter. The diamond-shaped spaces formed between the circular bins are also used for storage, each having a capacity of about 5 000 bushels. The bins, 92 ft. high, are surmounted by a cupola which houses the top conveyor and trippers, and extends the full length of the structure. With this the tanks are filled with grain. The bin walls are of concrete, 6 in. thick, with the customary reinforcement. Below the 12-in. reinforced concrete slab, which constitutes the bin bottoms, there are four conveyor-belt tunnels, 7 ft. wide, running the full length of the structure. These tunnels are formed by walls 16 in. thick and 7 ft. high, which rest on a 2-ft. mattress of concrete. Transverse to the main tunnel walls there are 15-in. cross-walls approximately 15 ft. from center to center. These are under the bin contacts. The tunnel or cross-walls were not bonded to the floor or bin slabs, and this constituted a considerable hazard during the straightening.

Excavation for the structure had been made to a depth of 12 ft. below the prairie level.

The dryer-house had broad footing courses under the walls. Although it was deemed advisable, later, to underpin this building, this presented no difficulty.

The Canadian Pacific Railway commenced storing grain in the binhouse in September, 1913. Considerable care was taken to regulate

FIG. 1.

the filling of the different tanks so as to distribute the load uniformly. Settlement began on October 18th. The bins at this time contained about 875 000 bushels of wheat. A vertical sinking of 1 ft. occurred within an hour after the settlement was first noted. This was followed by an inclination toward the west, which increased until, at the end of 24 hours, the binhouse rested at an angle of 26° 53′ from the vertical.

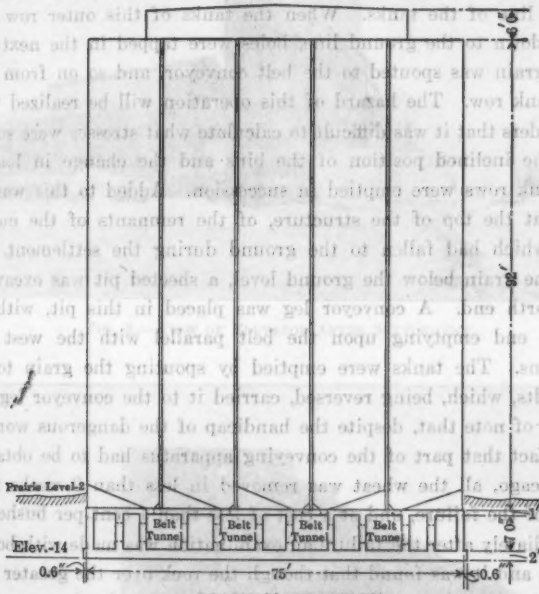

FIG. 2.

An examination showed the east side to be 5 ft. above, and the west side 29 ft. below, the original position; the building was also approximately 4 ft. lower at the north than at the south end. An upheaval of 5 or 6 ft. of the ground surrounding the bins occurred during the settlement. At an angle of 26° 53′ the center of gravity of the loaded structure had moved over almost to the low edge. The upheaval and the compacting of the soil along the west side saved it from completely falling over. Above this, on the west side, 52 ft.

of tank overhung the ground. This overhanging load, due to the grain-filled tanks, was considerable.

A careful examination was made of the structure and, remarkable as it may seem, practically no shear cracks were found. It was decided, therefore, that the first problem was to save the wheat. This was done by tapping the most westerly row of tanks at approximately the ground level and bleeding out the grain upon a belt conveyor parallel with the line of the tanks. When the tanks of this outer row were emptied down to the ground line, holes were tapped in the next row, and the grain was spouted to the belt conveyor, and so on from tank row to tank row. The hazard of this operation will be realized when one considers that it was difficult to calculate what stresses were set up, due to the inclined position of the bins and the change in loading as the tank rows were emptied in succession. Added to this was the menace, at the top of the structure, of the remnants of the cupola, part of which had fallen to the ground during the settlement. To remove the grain below the ground level, a sheeted pit was excavated at the north end. A conveyor leg was placed in this pit, with the discharge end emptying upon the belt parallel with the west side of the bins. The tanks were emptied by spouting the grain to the tunnel belts, which, being reversed, carried it to the conveyor leg. It is worthy of note that, despite the handicap of the dangerous working and the fact that part of the conveying apparatus had to be obtained from Chicago, all the wheat was removed in less than 3 weeks from the time of the failure, and at a cost of less than 1 cent per bushel.

Immediately after the failure an examination was made with boring machines, and it was found that though the rock over the greater area was at a depth of from 52 to 55 ft. below the prairie level, an unusual condition existed along about one-half of the length of the east side of the bins—a ridge of boulders some 12 ft. higher than the rock being encountered. This was the reason for the tipping over, for, as the initial vertical settlement took place, resistance was offered along the east side, probably through compacting the soil above the ridge of boulders. This produced a tendency of the building to cant to the west. The heavy load caused the clay to flow and the structure to settle.

Fortunately, the workhouse was only slightly affected by the movement of the binhouse. Only a few cracks showed in the north shed wall, no settlement taking place in the building proper.

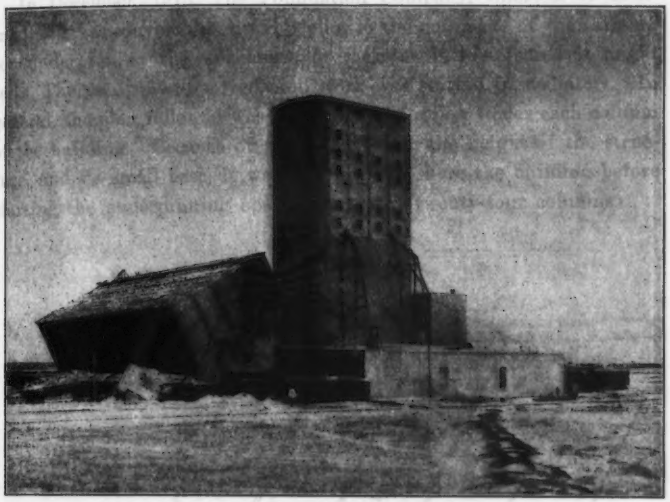

FIG. 3.—VIEW OF ELEVATOR AFTER SETTLEMENT.

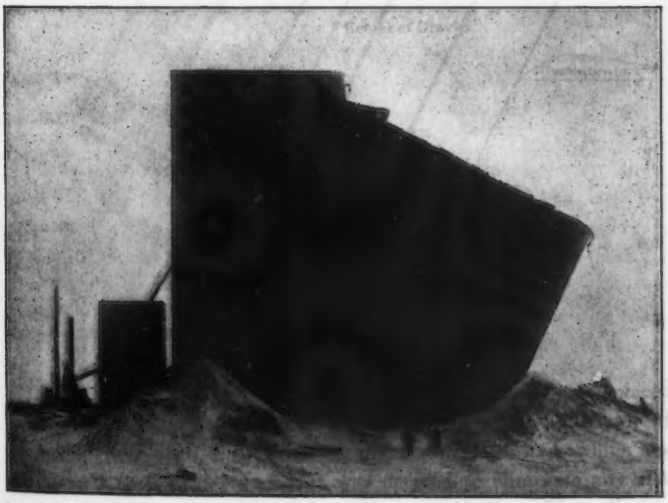

FIG. 4.—VIEW OF ELEVATOR AFTER SETTLEMENT.

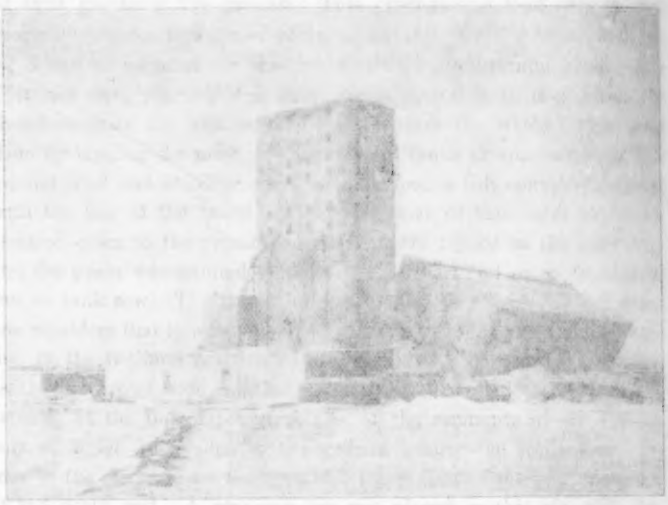

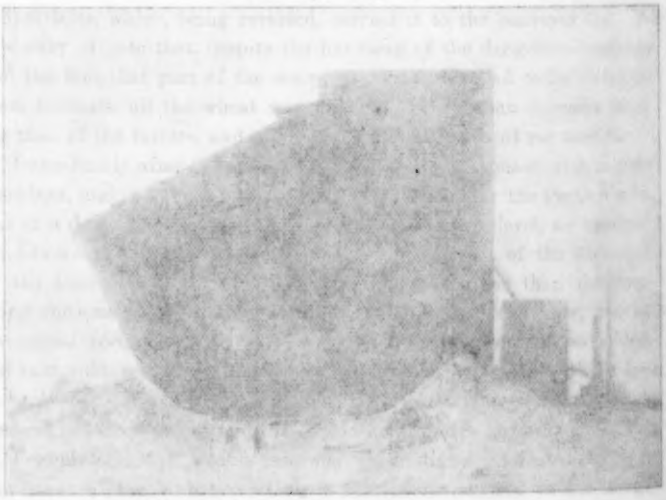

In December, 1913, The Foundation Company, Limited, of Montreal and Vancouver, submitted a plan to the engineers of the railroad for underpinning the workhouse to rock, as it was feared it might fall. The plan was approved, and work was started immediately. In general, the plan followed was the sinking of a pier under each column of the building. Because of the heavy loads, the height of the structure, and its small base, it was necessary to shore the building before starting the underpinning operations at the twenty-four columns.

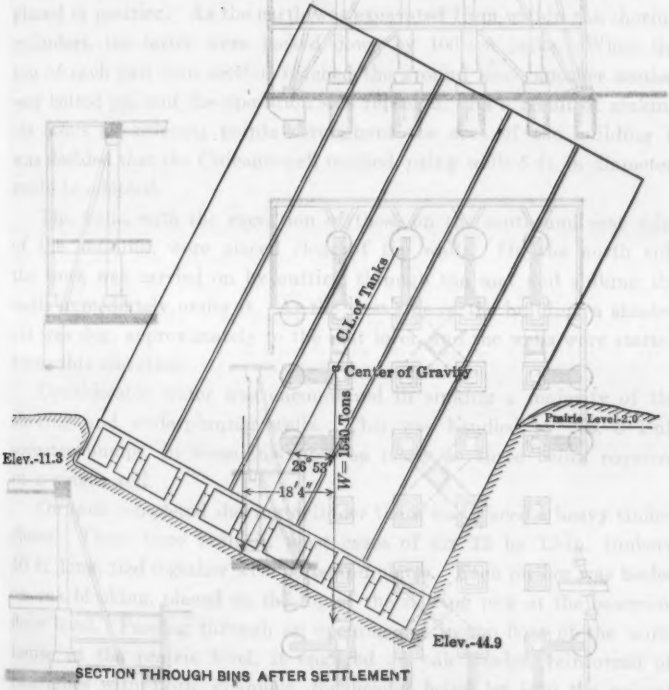

FIG. 5.

The shoring consisted of pushers from twenty small piers placed outside the building columns, as shown by Fig. 6. On account of the uncertainty of the condition of the material through which the piers would have to be carried, it was decided to eliminate any risk by sinking the first six with cast-iron shoring cylinders. The cylinders

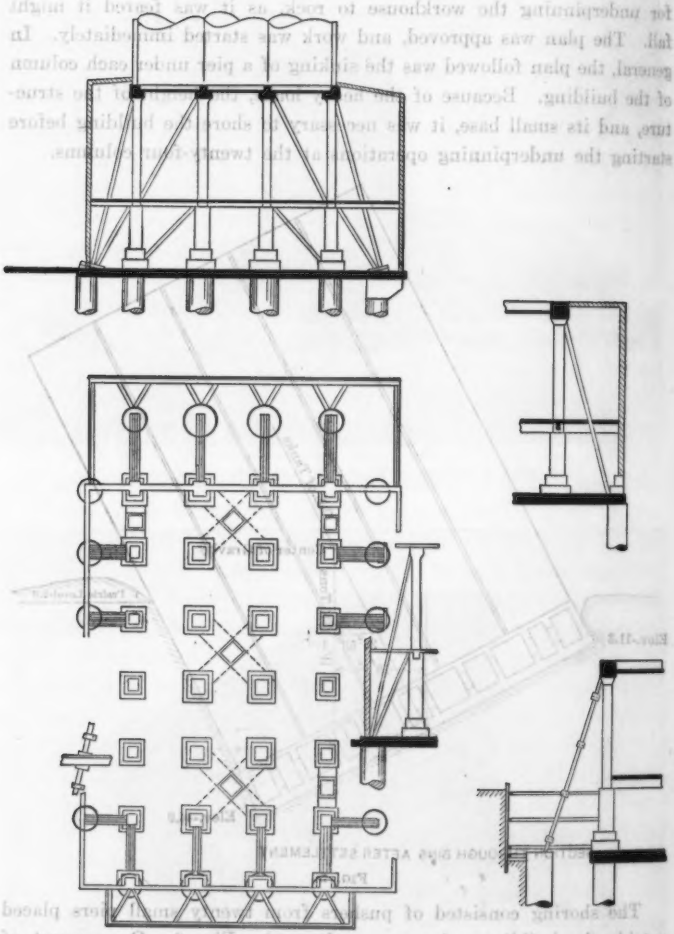

FIG. 6.

were 4 ft. in diameter, and built up in 3-ft. sections. Flanges were cast at each end of the sections for making connections. The one exception to this was at the bottom section, on which one flange was omitted, the unflanged rim being used as a cutting edge.

The shoring piers on the south and east sides were placed under the shed walls. Work on these was started by cutting a hole 4 ft. 6 in. square through the concrete floor, then drifting to the site of the pier. This excavation was sheeted, and the first section of the cylinders was placed in position. As the earth was excavated from within the shoring cylinders, the latter were jacked down by 100-ton jacks. When the top of each cast-iron section reached the ground level, another section was bolted on, and the operation was repeated. As a result of sinking six wells at different points throughout the area of the building it was decided that the Chicago well method, using wells 5 ft. in diameter, could be adopted.

The wells, with the exception of those on the south and east sides of the building, were placed clear of the walls. On the north side the work was carried on by cutting through the mat and sinking the wells immediately under it. At the west side of the building a sheeted pit was dug, approximately to the mat level, and the wells were started from this elevation.

Considerable water was encountered in sinking a majority of the shoring and underpinning wells. This was handled by No. 3 Pulsometer pumps, in some instances as many as three being required in a single well.

On each completed shoring cylinder there was placed a heavy timber shore. These were built in most cases of six 12 by 12-in. timbers, 40 ft. long, tied together with bolts and plates. Each pusher was heeled on oak blocking, placed on the top of the shoring pier at the basement floor level. Passing through an opening cut in the floor of the workhouse at the prairie level, it engaged an oak header, reinforced on two sides with 12-in. channels, the header being let into the column just below the bin floor by notching out the mushroom top, as shown by Fig. 7. Supplementing this was another pusher, extending from the shoring pier to the wall column at the first floor, and from this floor to the top of the interior column at the second-floor level.

Similar shores were placed on the shoring piers on all four sides of the building. These, combined with the columns, bin floor, and

reinforced mat, formed a truss arrangement by which the load of the building was largely transferred to the shoring piers. Later, while the interior piers were being sunk, timbers (shown by the dotted lines) were put in to take the load from the interior column bases.

All the shoring having been placed, the work of sinking the 5-ft. wells under the wall columns and the 6 ft. 6-in. ones under the interior columns was commenced. The columns are 15 ft. from center to center. To gain access to the under side of the exterior columns, holes 3 ft. 6 in. square were cut through the concrete floor mat between pairs of columns. Drifts 4 ft. wide and 6 ft. deep were driven in the direction of each column. As a well site was reached, the space was enlarged to a circular area slightly greater than the outside diameter of the well lagging. These drifts or tunnels were sheeted to prevent loss of ground, and afforded the only means of communication with the wells. The excavated material was hoisted in light galvanized-metal buckets which traveled on curved tracks or skidways, necessary on account of the center of the top of the underpinning well and opening in the floor being off center by 7½ ft. At the basement floor level the spoil was dumped into wheel-barrows, which were wheeled to a motor hoist, raised to the prairie level, and wasted at a short distance.

Prior to opening up the wells at the workhouse, levels had been taken on the column footings. As the piers were sunk, check levels were taken at regular intervals. As a further check on any movement, a plumb-bob weighing 280 lb. was suspended from the roof of the building down through an elevator shaft. The total distance was about 160 ft. The plumb-bob was immersed in a tank of water which was prevented from freezing by an electric coil. The position of the bob was noted every day.

Wells under the interior columns were approached in the same manner, except that the holes through the floor mat were cut centrally with respect to four columns, and handled the wells under them by drifting to each site in turn as one after another of the wells was completed. The distance from the center of the floor opening to the center of each underpinning pier in this instance was 10 ft. 6 in. Special curved skidways were used for these wells also. In all cases single-drum hoists, electrically operated, and having a rope speed of 130 ft. per min., were used to elevate the excavated material.

FIG. 8.—TRENCH, WITH BELT CONVEYOR, ALONG EAST SIDE OF BINHOUSE.

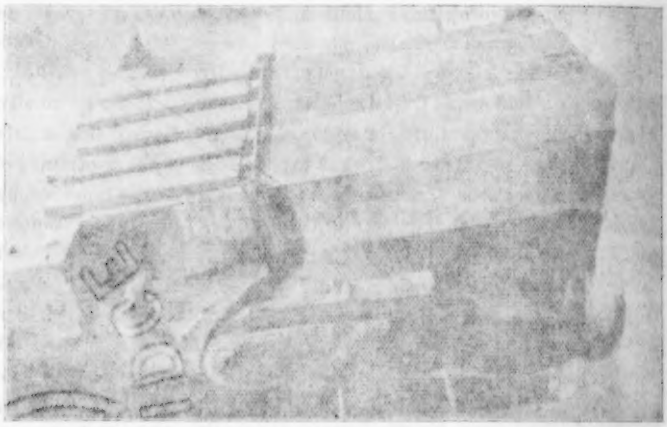

FIG. 1.—LANDING FOR AN AUTOMOBILE FERRY

FIG. 2.—TIMBER PIER UNDER CONSTRUCTION

Concrete, up to the top of the wells, was deposited through light 8-in. galvanized-iron pipe, cut to short lengths to accommodate them to the necessary curvature. Above this elevation, and up to within 8 in. of the under side of the columns, concrete was shoveled into place behind forms, the near side of which was built up as the concreting progressed. After this concrete had set sufficiently, the remaining 8 in. were finished both by grouting and by ramming in fairly dry concrete.

The workhouse operations were completed by about the beginning of June, 1914.

In the latter part of Feburary, 1914, permission was given to The Foundation Company, Limited, to proceed with the straightening of the binhouse. When the vertical position had been reached, it was planned to underpin it also by concrete piers to rock, these piers to be placed under the contact points of the tank walls in longitudinal rows. As a matter of economy, it was decided not to attempt to raise the building to its former elevation, but to straighten the structure by rotating it about the low edge; this was to be accomplished by excavating under the east or high side, and lowering it to the level of the low or west side. This meant that the mat in its final position would be approximately 38 ft. below the prairie level. As this was below the ground-water line, it was proposed to water-proof it.

The binhouse when empty of grain weighed 20 000 tons. Under the lower or west edge of the mat fourteen piers were sunk to rock and concreted. It was the intention to block the building off these piers to form a fulcrum, about which it would rotate as the excavating was done under the high side. The clay actually under the mat was removed in two ways: First, by working from under the high edge of the mat; and secondly, through holes in the mat. The former necessitated the excavation of a trench paralleling and flush with the east edge, as shown by Fig. 8. This was carried to a depth of about 8 ft. below the mat edge, was approximately 10 ft. wide at this point, and sloped back on the side away from the structure to the natural angle of repose of the soil. Drifts were driven from the trench toward the west under the mat. In the trench was placed a belt conveyor which discharged upon another belt, at the north end of the building, running at right angles to the first one. This second belt emptied into a hopper from which the earth was hauled by team

and spread over the prairie. The holes in the floor were in the compartments formed by the cross-walls between those of the main tunnels. The spoil passed through the holes and was handled by two conveyor belts, one in the first and the other in the third tunnel from the east. These belts discharged upon the transverse belt, previously mentioned as running along the north end. The gradual settlement of

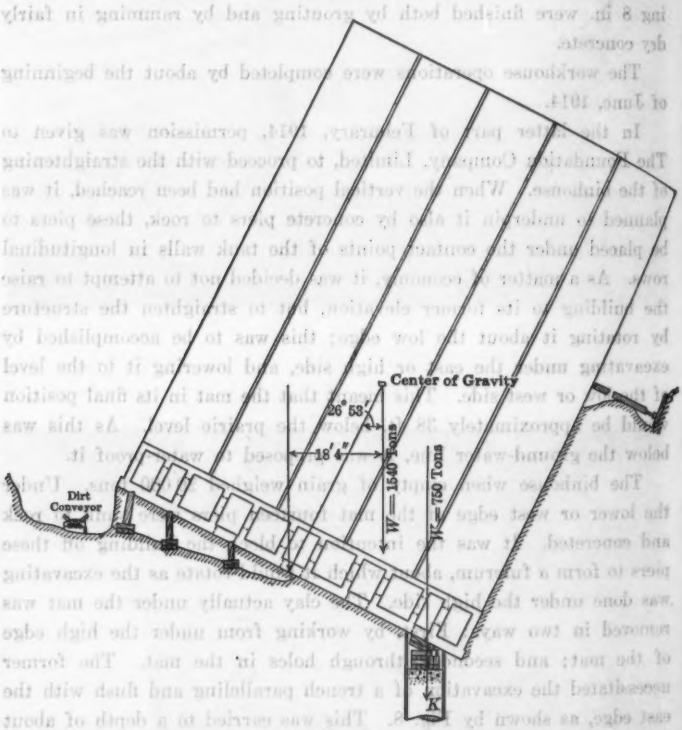

FIG. 9.

the high side was to be accomplished by weakening the core of earth left between the drifts. In driving the drifts, the earth wall between them was narrowed from the bottom up, the intention being that, as the building dropped, this core would offer increasing resistance to the movement, and that this movement could be controlled by removing the earth from the sides of the cores.

The fourteen piers under the low side, known as the *K* row, were placed on the longitudinal center line of the thirteen tanks, as shown by Fig. 9. They were placed under the contact walls and at the ends. Access to the sites of these wells was secured by cutting holes, 3 ft. 6 in. by 4 ft., through the mat in the compartments between the tunnels proper. The experience gained in sinking the workhouse wells showed that a large quantity of water would have to be handled in sinking the wells of the *K* row. Preparations for doing this were made by lagging down a large sump with 10 by 10-in. timbers at the north end of the building. This sump was carried to the depth of the low corner of the mat. It was placed inside the excavation which had been made to put in the grain leg and also the transverse belt conveyor used in connection with handling the spoil. In the sump was erected a duplicate set of electrically-driven centrifugal pumps and steam-driven piston pumps. Each set had a capacity of 1 200 gal. per min.

In sinking the wells of the *K* row, as well as the others described later, the work was performed under considerable difficulty, owing to the 27° inclination of the mat and the confined working space. Spoil from the different wells was raised by hand windlasses. The limited space and the small quantity of material to be handled would have made any mechanical arrangement more expensive.

The depth of sinking at the *K* wells was only 14 ft. Lagged wells of the Chicago type, 7 ft. in diameter, were used. The material was found to be very firmly compressed; in some instances the blue clay had been driven into the white stratum. The white clay, instead of being soft, as it had been found at the workhouse, was squeezed dry and hard, so that it was usually necessary to pick before shoveling into the buckets. No water was found until the shattered limestone stratum, immediately overlying the rock, was reached.

Not only was a large quantity of water found in the *K* wells, which from No. 1 to No. 6 came in at the rate of 1 150 gal. per min. in each well, but, in addition there was the danger that the level to which it would normally rise was approximately 14 ft. above the mat at the openings. This made imperative the duplicate pumping system at the sump. The insufficiency of room further aggravated the water troubles.

To do away with the multiplicity of piping of the small steam units and the almost unbearable heat from them, belt-driven, electrically-operated centrifugal pumps were erected immediately above the wells. These were placed on the main tunnel floors, and independent holes for the pump suctions were cut through the mat. As it was considered inadvisable to open up too many wells at one time, alternate ones only were started. As the concreting of these piers was finished, oak cribs were placed upon them to take the load of the building, as shown by Fig. 9.

As the work on the *K* piers was nearing completion and the majority of them had been blocked up, the construction of the remaining 56 piers was commenced, it being the intention to sink these piers while the righting process was under way. These were opened up as far as possible in widely scattered positions. Although quantities of water were encountered, particularly at the north end of the building, the working conditions were somewhat better than at the *K* row, and the work progressed steadily. These wells were also 7 ft. in diameter; they were placed under the contact walls and tank ends, and were in all cases carried to rock. They were arranged in four rows, starting from the east, and designated as *G*, *H*, *I*, and *J*.

At about this time the original plans were changed, owing to the fact that the railroad engineers had decided that they would prefer to have the tunnel floors above the ground-water level. To accomplish this the new plan contemplated allowing the bins to rotate about the *K* row until the angle, 16° 30′, had been reached, at which time the binhouse was to be pivoted about the *I* row of piers to an angle of 8° 30′. At this point the structure was to be again pivoted about the *H* row of piers into a vertical position.

As the drifts or tunnels were driven under the high side of the mat, 12 by 12-in. posts were set up in them on mudsills of such an area that the load imposed on the soil was about 3 tons per sq. ft. See Fig. 10. These helped to make up for that resistance against the mat which was lost as the drifts advanced. Later, as the excavation was extended so that the sinking of the wells in the *G*, *H*, *I*, and *J* rows could be proceeded with, more posts on mudsills were added, for the same reason.

The number of posts put in also enabled the settlement of the structure to be closely regulated. This was preferable to depending

FIG. 10.—EXCAVATION TOWARD WEST FROM UNDER EAST EDGE OF MAT.

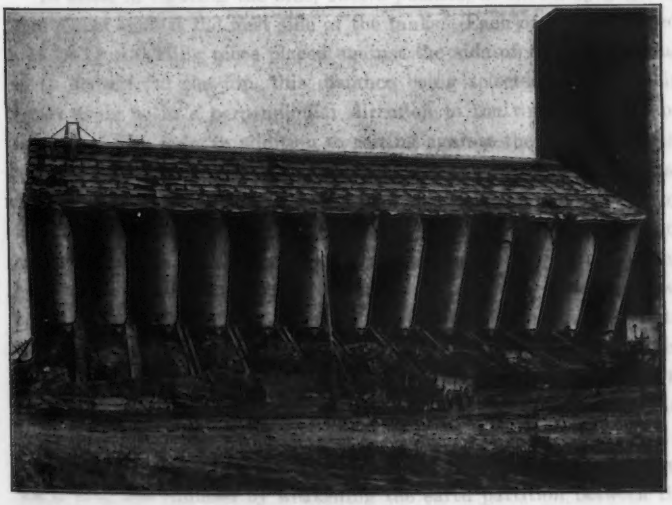

FIG. 11.—LINE OF PUSHERS AGAINST WEST SIDE OF BIN STRUCTURE, SHOWING HOLES THROUGH WHICH GRAIN WAS TAKEN OUT.

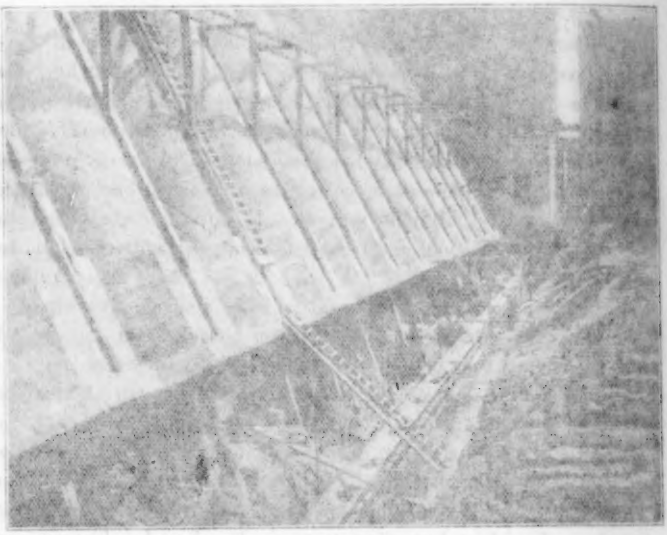
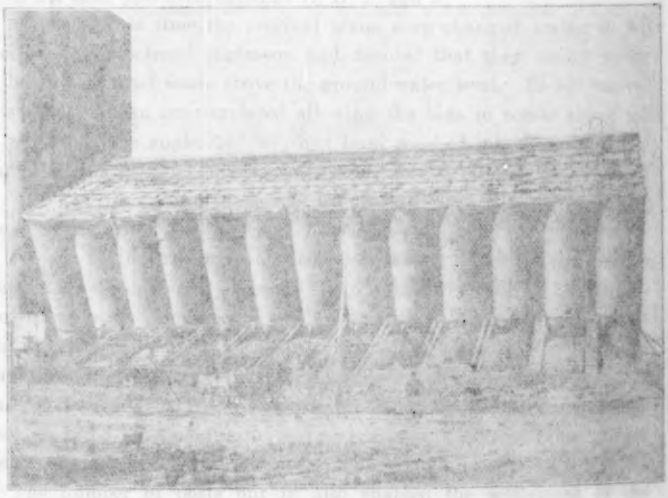




only on the clay ribs, which, on occasions, had a tendency to break off in large masses. This fracturing of the clay cores also necessitated increasing the number of posts.

The posts as well as the shoring screws, mentioned later as being placed on the *G* and *H* piers, were also necessary on account of the fact that the reinforced mat, tunnel walls, and bins were not tied together vertically in any manner. Without some such precaution the mat could have broken off, or the three parts could have slid on one another.

With the bins at rest at the angle of 26° 53′, calculations showed that the loads at the pier sites were as follows:

Those in	*G*	row.....	Uplift
" "	*H*	"	11 tons per pier.
" "	*I*	" 227	" " "
" "	*J*	" 529	" " "
" "	*K*	" 773	" " "
Total per transverse row....1 540 tons.			

To assist in righting the bins, twelve pushers, as shown by Fig. 11, were placed against the west side of the tanks. Each of these engaged a 12 by 12-in. waling piece placed against the side of the tanks about 45 ft. down from the top, this distance being selected so that their forces would be in a perpendicular direction to the vertical height of the tanks. The wale, in addition to resting against the thirteen tanks, was also posted into the contact walls, for it was at these points that the pushers were applied. Each pusher was composed of two 12 by 12-in. timbers, spaced 12 in. apart by using spreaders of that dimension, and tied together by plates and bolts. Each was 60 ft. long, and each had two screws, one in each of the 12 by 12-in. timbers, these screws heeling against ample timber mats. The screws were operated until the mat had reached an angle of 8° 30′. The line of action of the pushers was lowered once during the righting operation so as to maintain as nearly as possible their perpendicular direction against the sides of the tanks.

The initial righting movement, namely, that of rotating about the *K* row, was induced by weakening the earth partition between the drifts. Practically, a continuous daily movement of from 3 to 4 in.,

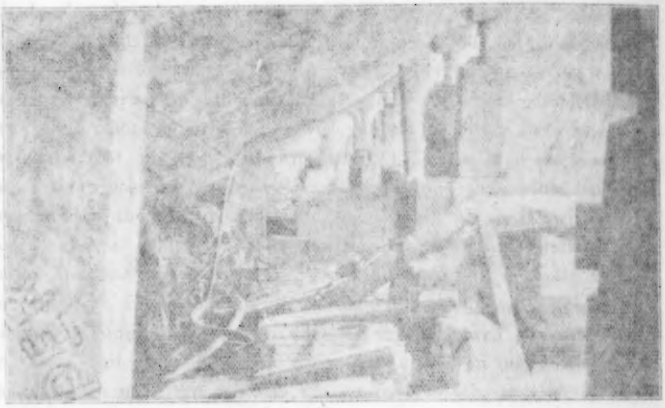
at the eastern edge, was maintained. When the bin floor had reached an angle of 18°, the movement was stopped for the purpose of placing the hardwood rockers at the *I* row of piers.

During this initial movement all the wells under the mat were successfully bottomed and concreted to the heights required for carrying on the work. As rapidly as the *G* and *H* rows were completed, cribwork was placed on each pier, with 40-ton shoring screws in contact with the mat, as shown by Fig. 12. These screws made possible a much more positive control in lowering the mat than could have been attained by the clay rib alone. The placing of the shoring screws and posts on mudsills also permitted the removal of all the clay under the mat back to the west side of the *H* row of wells, approximately 23 ft. from the edge of the mat. The removal of this excavation from under the eastern edge of the mat was thus carried on more economically than if the excavation had been made through the holes in the mat. In fact, as the lowering of the mat continued, a uniform depth of the clay of approximately 8 ft. from the outer edge and 4 ft. at the line back of the *H* row was maintained—the belt conveyor used for the disposal of the material being also lowered from time to time as the general excavation progressed.

Shortly after starting to rotate the structure about the *K* row, readings showed that a lateral or sliding movement to the eastward had set up. This was hard to understand, on account of the inclination of the bins to the west; also because of the compressed clay fronting the under side of the mat, and the fact that the dead load of the structure was 20 000 tons. Notwithstanding this, however, the tendency was always in evidence until the structure was pivoted on the *I* row of piers. To resist the movement, 12 by 12-in. timber kicking braces (Fig. 13), usually arranged in pairs, were used. These were of two lengths: short ones engaging the high edge of the mat, and long ones reaching in under the mat to notches cut in its under side, as shown by Fig. 14. In both cases they heeled against the earth embankment on the far side of the trench, where liberal timber heels had been set up. To retard the lateral movement still more, short inclined posts were set up on the *K* piers, their upper ends engaging notches cut in the mat. In addition, approximately 3 000 cu. yd. of earth, pressing against the bins along the west side, were removed. This total lateral movement to the west finally amounted to 3 ft. 3 in.

FIG. 12.—SHORING SCREWS, ON "G" ROW OF PIERS, CARRYING EDGE OF MAT.

FIG. 13.—KICKING BRACES AGAINST EASTERN EDGE OF MAT AT BINHOUSE.



On August 13th the structure was brought to rest at an angle of 18° by using cribbing placed on the *J* row of piers. There were two of these cribs on each pier, and they were placed in a direction transverse to the longitudinal axis of the bins. They had a total area in plan of 4 by 7 ft. The rear one was 2 by 4 ft., and was removed later to give room for the shoring screws; the former one was used for following up with blocking as the structure rotated about the *I* and *H* rows of piers.

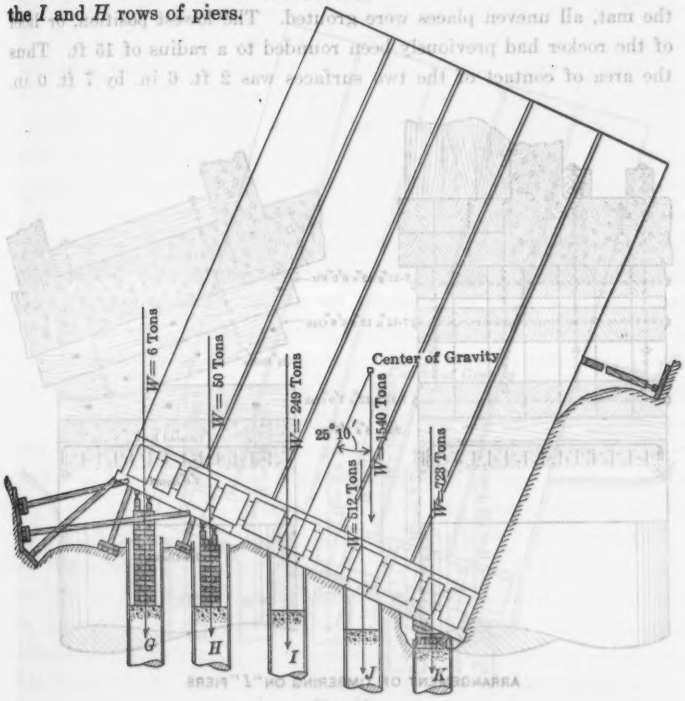


FIG. 14.

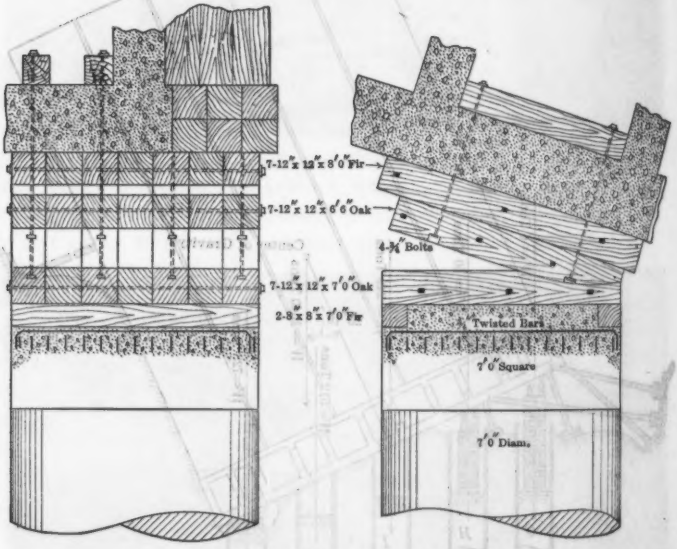
To form convenient working places, all the tops of the piers were made 7 ft. square. In preparing the piers for the rockers, as shown by Fig. 15, 8 by 8-in. timbers were embedded in the edges parallel to the longitudinal axis of the bins. The rockers consisted of two parts: the shoe and the rocker proper. The former was made by covering the top of each pier with 12 by 12-in. oak timbers, laid in

the direction of the movement and strongly bolted together. The upper surface of this shoe was concaved to a radius of 30 ft., and also in the direction of the rotation.

The rockers consisted of two courses of 12 by 12-in. oak timber, seven pieces in each course, directly above the timbers in the shoe. These two courses were strongly bolted together and also to the mat. To make certain of an even bearing against the rough bottom of the mat, all uneven places were grouted. The lowest position, or heel of the rocker had previously been rounded to a radius of 15 ft. Thus the area of contact of the two surfaces was 2 ft. 6 in. by 7 ft. 0 in.



ARRANGEMENT OF TIMBERING ON "I" PIERS

FIG. 15.

Clearance was allowed between the rockers and the shoe, so that contact was not made until the bins reached an angle of 16° 30'. The allowance was made in order to provide for the possibility of a slight settlement during the time required to set up the rockers. When the mat had reached this angle, the center of gravity had shifted to a position 11 ft. 3 in. west of the center of the structure. At the angle

of 26° 53′, it had been 18 ft. 4 in. to the west. In the new position the figured pressures on the piers (see Fig. 16) were as follows:

G.....	80 tons.
H.....	193 "
I.....	316 "
J.....	423 "
K.....	528 "

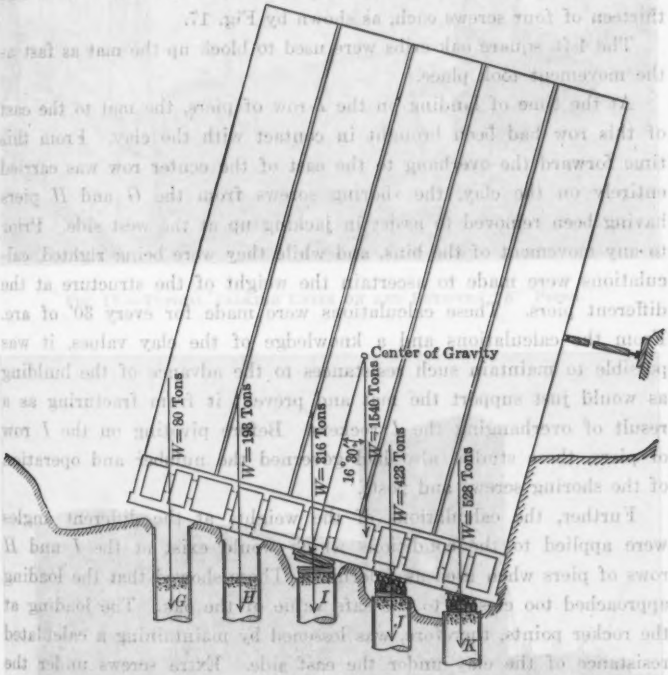


FIG. 16.

The rockers on the *I* row having been completed, the next step consisted in preparing the *K* and *J* rows for the shoring screws. Excavation to a depth to give ample room was made from the east face of the *J* piers to the west face of the *K* piers. This excavation stepped up as the *J* piers were approached, so as to maintain a practically constant head room and reduce the quantity of back-fill required later.

Between the piers of the *K* row the excavation exposed the white clay, previously mentioned as having been very much compacted. Over the clay and extending from pier to pier throughout the total length of the *K* row was laid 1 ft. of concrete. On these slabs were placed oak timbers, and on the latter four 50-ton shoring screws were set up. Twelve 50-ton screws, surrounding oak cribs 4 ft. square, were placed on the *K* and *J* piers. At the time of starting the movement there were, therefore, twenty-eight jacking units of twelve screws each and thirteen of four screws each, as shown by Fig. 17.

The 4-ft. square oak cribs were used to block up the mat as fast as the movement took place.

At the time of landing on the *I* row of piers, the mat to the east of this row had been brought in contact with the clay. From this time forward the overhang to the east of the center row was carried entirely on the clay, the shoring screws from the *G* and *H* piers having been removed to assist in jacking up at the west side. Prior to any movement of the bins, and while they were being righted, calculations were made to ascertain the weight of the structure at the different piers. These calculations were made for every 30′ of arc. From the calculations and a knowledge of the clay values, it was possible to maintain such resistances to the advance of the building as would just support the mat and prevent it from fracturing as a result of overhanging the *I* rockers. Before pivoting on the *I* row of piers, these studies also had governed the number and operation of the shoring screws and posts.

Further, the calculations of the weights at the different angles were applied to the conditions which would exist at the *I* and *H* rows of piers when used as fulcrums. These showed that the loading approached too closely to the safe value of the oak. The loading at the rocker points, therefore, was lessened by maintaining a calculated resistance of the clay under the east side. Extra screws under the low side were used to overcome this resistance.

The righting operations were continued, both by lessening the resistance of the clay under the overhanging portion of the mat and by jacking up the low side. Trenches were excavated under the mat from the *H* rows of piers eastward. These trenches extended to within about 3½ ft. of the east edge of the mat, and averaged 4 ft. in depth, except when the mat was approaching the horizontal position, when

FIG. 17.—TYPICAL JACKING UNITS ON AND BETWEEN "K" PIERS.

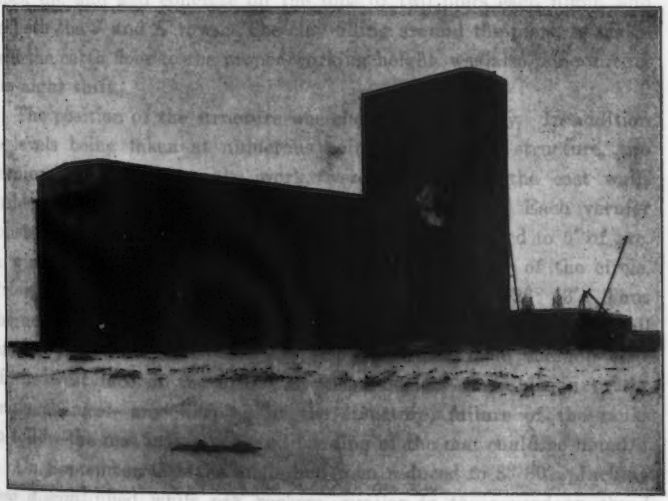

FIG. 18.—STORAGE BINS IN RIGHTED POSITION.

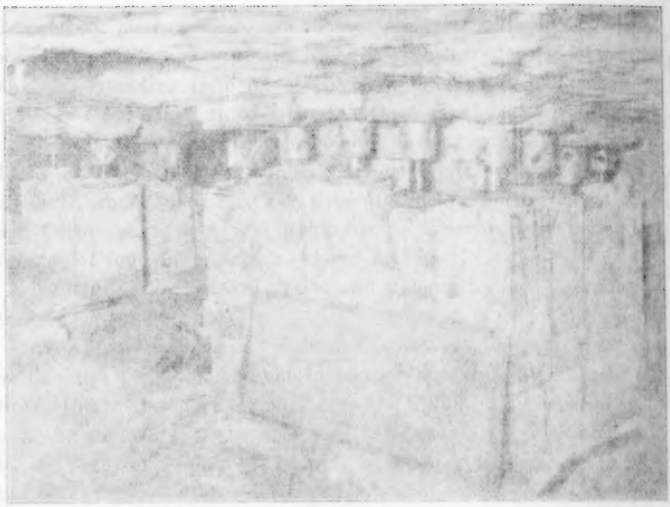

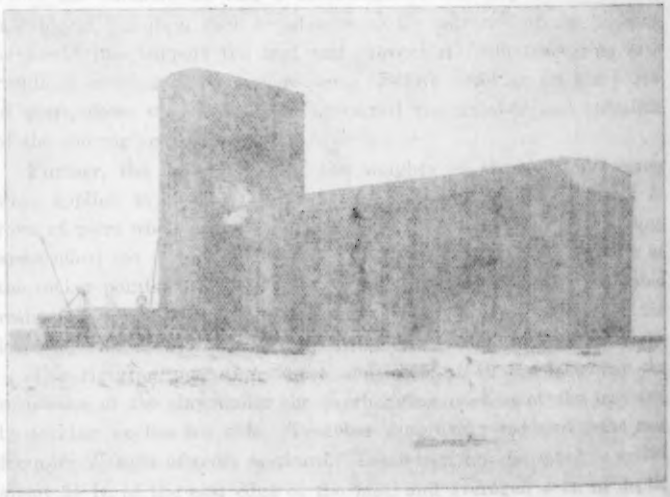

they were allowed to fill. The bank of clay between the *H* and *I* rows was left in place. The width at the bottom of the trenches averaged about 3 ft., the sides being sloped so that each rib between two trenches had a triangular section. Continuous weakening of the clay ribs and deepening of the trenches was maintained at a rate practically equivalent to the uplifting thrust of the shoring screws. Spoil from the trenches was handled through holes in the mat.

The jacking part of the lifting operation was done by gangs made up of three men. Each gang was supplied with a 6-ft. steel bar 1⅛ in. in diameter, which, when inserted in the head of the shoring screw with three men pulling on it, was equivalent to an effort of approximately 55 tons. In the *K* row each gang handled eight screws, and six was the allotment for the *J* row. The periods of work and rest were carefully arranged, and a uniform application on the screws throughout the total length of the bins was maintained during such periods. The jacking-up process was only carried on during the day shifts. At the same time, six gangs of two men each were kept busy fleeting the screws and following up with oak blockings as progress was made. The night shift was utilized to fleet the screws, block up, and add concrete on the tops of two piers each night, and on both the *J* and *K* rows. The clay filling around the piers, to maintain the earth floor to the proper working height, was also done during the night shift.

The position of the structure was checked twice daily. In addition to levels being taken at numerous points around the structure, two verniers, fabricated on the work, were attached to the east walls inside of the north and south tanks of the *G* row. Each vernier consisted of an arc of a circle of 15 ft. radius, graduated to 5′ of arc. A wire with weighted lower end hung from the center of the circle. Prior to any movement of the bins, this had been set to 26° 53′. Thus the actual angle of the structure could be ascertained quickly at all times. A 240-lb. plumb-bob was also suspended from the top edge of the west face of the bins. By these devices—in addition to the angle changes—any warping of the structure, failure of the tanks to follow the mat movement, and bending of the mat could be noted.

On September 17th the angle had been reduced to 8° 30′. Jacking was discontinued while oak rockers, similar to those used on the *I* piers were placed on the *H* piers. As in the previous case, at the *I*

piers, allowance had been made for the creeping of the structure during the time it took to place the rockers, and they did not come to a full bearing until the angle 7° 30′ had been reached. The shoring screws were now removed from the pushers at the west side of the building and set up on the *I* piers. The grouping of screws during this, the final movement, was as follows: *K* piers, each twelve screws; *J* piers, each ten screws; and *I* piers, each eight screws. At this angle (see

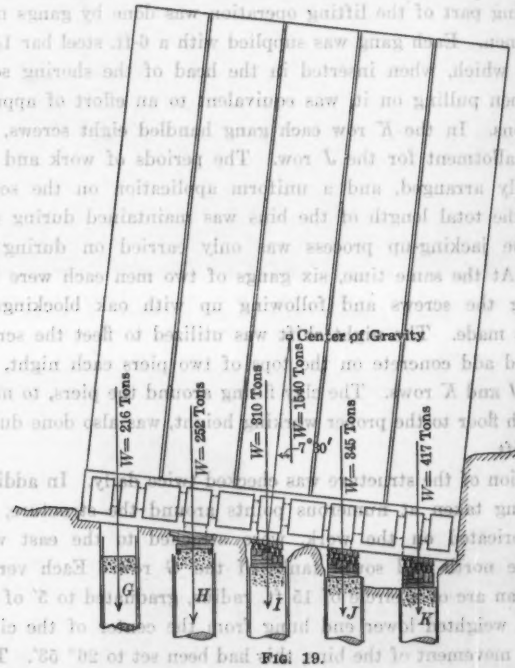

FIG. 19.

Fig. 19) the pier loading was as follows: *G*, 216 tons; *H*, 252 tons; *I*, 310 tons; *J*, 345 tons; and *K*, 417 tons. The center of gravity, in the meantime, had shifted until at this angle it was only 3 ft. 3 in. west of the center line of the structure. During this last operation it was found advisable to assist the screws on the *I* piers by using oak wedges, 4 ft. long, 6 in. wide, and 3 in. thick at the butt end; these were driven between the shoe and the rocker on these piers. This was made necessary on account of the tendency of the mat to sag.

FIG. 20.

An average rate of 4 in. in 10 hours, measured on the center line of the *K* piers, was maintained throughout the jacking portion of the righting operation. The binhouse was back in its proper vertical position on October 17th, 2 days behind the estimated time. After the building had been righted, the screws and blocking were removed from piers in scattered locations. In concreting up to the under side of the mat, these piers were corbeled out, so as to distribute the pressure, as shown by Fig. 20. The building as it stands to-day is practically 14 ft. below its original position, the total lift having been a trifle more than 12 ft.

To meet the new elevation of the tunnels, excavation was made in the workhouse, and the grain boots were lowered to receive the discharge from the tunnel belts. Also, to provide for the overhang of the bins on the east side, caused by the lateral movement, seven piers were constructed with corbeled tops to carry the outer points of the tanks.

The inclination of the bins to the north, amounting to 4 ft. in their total length, was allowed to remain. This does not affect the stability of the structure, nor the cost of handling the grain, so that any additional expense to get the structure exactly level north and south would have been unwarranted.

At the north end of the structure, an areaway, 6 ft. wide and 52 ft. long, was built to a height of 15 ft. above the tank bottoms. This was roofed over with concrete, 2 ft. 6 in. above the top of the walls, the open space being left open for the ventilation of the tunnels. At the bottom of the areaway was built a sump. This extends 7 ft. below the mat, and is 6 ft. wide and 21 ft. long. Here were installed two No. 4, motor-driven, submerged type, centrifugal pumps, having a rated capacity of 470 gal. per min. As shown by Fig. 20, no attempt was made to back-fill around the tanks to the prairie level. Leaving the depression as shown precluded the necessity of water-proofing the tanks, which would have been necessary to protect the grain had the soil been allowed to come in contact with the thin walls. It will be noted that a berm 8 ft. wide was left around the structure. This slopes away from the bins, and forms a drain for carrying the surface water to catch-basins placed just outside of the north areaway, whence it is piped to the sump.

DISCUSSION

Mr. Gutman.

DAVID GUTMAN,* M. AM. SOC. C. E.—The speaker once had an experience with the sinking of the foundation of a building which, although of a different nature from the grain elevator under discussion, had one point in common, in that the structure acted as a monolith.

About 4 years ago, he was designing engineer for the architect on the Taft Hotel, at New Haven, Conn., a fourteen-story structure with two basements. The framework was of steel, and the floor-slabs were of the long-span type formed of concrete beams, 16 in. on centers, with a tile filler between. The foundations consisted of cast bases resting on reinforced concrete piers, the piers resting on sand. In the boiler-room the tops of these piers were about 4 ft. below the water line. The piers were placed by draining the water to a sump and pumping day and night. The basement was then water-proofed by placing felt water-proofing on a concrete mattress. The water-proofing was in turn held down by a concrete floor, the reinforcement being inverted, as the load—that is, the water pressure—was from below.

Early one morning, the speaker, who was in New York, received an urgent telephone call to visit the job at once, and on his arrival found that one of the concrete piers had dropped more than 2 ft., taking the cast base with it and leaving the column suspended in mid-air. The column itself had sunk about 2½ in.

The column was of the I-type, and had a girder running into each flange, the depth of the girders varying from 15 to 20 in. on the different floors. It was evident that the column no longer acted as such, but simply as a link between the two girders, making them one continuous girder of 32 ft. span, instead of two girders of 16 ft. span each. No wind bracing had been provided, other than a very stiff girder connection to the columns. One of the features of this connection was a 6-in. outstanding leg for the angle-seat and top-lug, having four rivets instead of the usual two. It was this stiff connection, as well as the excellent floor-slab (from 7 to 9 in. deep), which made the continuous action possible and prevented a very serious collapse.

The cause of the sinking of the foundation—a concrete pier 10 by 10 ft.—was as follows: The felt water-proofing had been pierced in some way, and this allowed a gradual seepage of water which accumulated in the cellar. In order to get rid of this water the pump was again set going, but, through negligence, the damage was not repaired at once, the work being delayed almost a month. Of course, some sand was pumped in with the water, and gradually the pier was undermined.

* Mount Vernon, N. Y.

Mr. Gutman. Two heavy plate girders were placed on opposite sides of the column, spanning to the two good piers on each side. These girders were then riveted to the column, and jacks were placed under the ends. By these jacks, the column was pushed up about ¾ in. It was not considered wise to raise it the whole amount of the settlement—2½ in.—as this would have cracked the plaster on the upper floors, most of which had already been placed. The piers on each side showed no settlement whatsoever, either before or after the jacking.

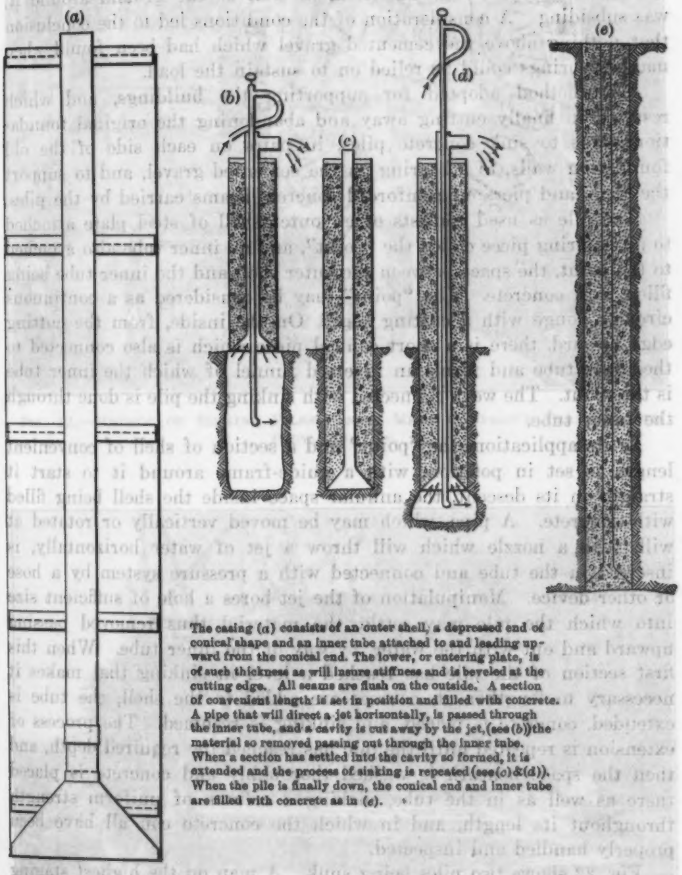
Mr. Phillips. W. R. Phillips,* M. Am. Soc. C. E. (by letter).—A brief description of some work brought about through the failure of the foundations at the Union Meat Company's plant may be of interest in connection with the discussion of this paper. The cases were to some extent similar, although the manner of sinking the new foundations was different. Unlike the work at Winnipeg, this was handled entirely from the surface, and was independent of underground conditions, such as water, depth, or material, so long as the latter could be cut by the jet.

The plant of the Union Meat Company is housed in a group of buildings suited to the packing business, and is on the south shore of Oregon Slough, Columbia River, at North Portland, Ore. The principal buildings of the group are the main packing house and the tank house. The former is 122 by 166 ft., and, in its highest part, has seven floors. The latter is 33 by 52 ft., and has four floors.

As designed originally the buildings were to rest on concrete foundations of considerable depth, supported by wooden piles. The piles were properly driven and, after the foundations were built, the spaces between and around the walls were filled with sand dredged from the river. In preparation for the work, wash borings had been made to a depth of 116 ft. below the surface of the ground, where cemented gravel was found. The borings produced nothing to indicate that the ground would not remain stable under the load to which it was to be subjected, and, in this case at least, may be considered as an illustration of unreliability in a test of this class, as the condition on which the ground depended for its stability was not such as would be readily discovered by wash borings. It was not until the concrete piles for the new foundation were being sunk that the clue was obtained whereby the condition that might be responsible for the subsidence was discovered. During that process a horizontal stratum of dense material about 6 ft. thick, was found at a depth of about 65 ft. below the surface, and, as it happened, just beneath the ends of the wooden piles, which aroused suspicion that the water beneath it was sustaining the ground, and that the water was being slowly displaced by the added load. The correctness of this theory was seemingly demonstrated by sinking

* Portland, Ore.

Mr. Phillips.



The casing (*a*) consists of an outer shell, a depressed end of conical shape and an inner tube attached to and leading upward from the conical end. The lower, or entering plate, is of such thickness as will insure stiffness and is beveled at the cutting edge. All seams are flush on the outside. A section of convenient length is set in position and filled with concrete. A pipe that will direct a jet horizontally, is passed through the inner tube, and a cavity is cut away by the jet, (see (*b*)) the material so removed passing out through the inner tube. When a section has settled into the cavity so formed, it is extended and the process of sinking is repeated (see (*c*) & (*d*)). When the pile is finally down, the conical end and inner tube are filled with concrete as in (*e*).

FIG. 21.

Mr. Phillips.

a pipe through the dense material. In this pipe water was found to stand at a height of 10 ft. above that of the adjacent slough.

Not until sand was dredged in to fill around the foundation was there evidence of settlement, but with that to start it, it was soon demonstrated that the foundation, as well as the ground around it, was subsiding. A consideration of the conditions led to the conclusion that nothing above the cemented gravel which had been found when making borings could be relied on to sustain the load.

The method adopted for supporting the buildings, and which resulted in finally cutting away and abandoning the original foundations, was to sink concrete piles, in pairs on each side of the old foundation walls, to a bearing on the cemented gravel, and to support the walls and piers on reinforced concrete beams carried by the piles.

The pile as used consists of an outer shell of steel plate attached to an entering piece called the "point", and an inner tube also attached to the point, the space between the outer shell and the inner tube being filled with concrete. The "point" may be considered as a continuous circular gouge with a cutting edge. On the inside, from the cutting edge upward, there is a short conical piece which is also connected to the inner tube and forms an inverted funnel of which the inner tube is the spout. The work connected with sinking the pile is done through the inner tube.

In its application, the "point" and a section of shell of convenient length is set in position, with a guide-frame around it to start it straight in its descent, the annular space inside the shell being filled with concrete. A pipe, which may be moved vertically or rotated at will, with a nozzle which will throw a jet of water horizontally, is inserted in the tube and connected with a pressure system by a hose or other device. Manipulation of the jet bores a hole of sufficient size into which the pile may settle, the material thus removed passing upward and out with the water, by way of the inner tube. When this first section of the pile has reached a level in sinking that makes it necessary to lengthen it, courses are added to the shell, the tube is extended, concrete is placed, and sinking is resumed. The process of extension is repeated until the pile has reached the required depth, and then the space beneath is washed thoroughly and concrete is placed there as well as in the tube, making a column of uniform strength throughout its length, and in which the concrete can all have been properly handled and inspected.

Fig. 22 shows two piles being sunk. A man on the highest staging is manipulating the jet pipe with a wrench. The pile to the left has been sunk to a point where it requires to be extended. The inner tube has been lengthened, and courses are to be added to the outer shell. This will then be filled with concrete and the sinking will be resumed.

FIG. 23.—METHOD OF FORCING A PILE BY LOADING.

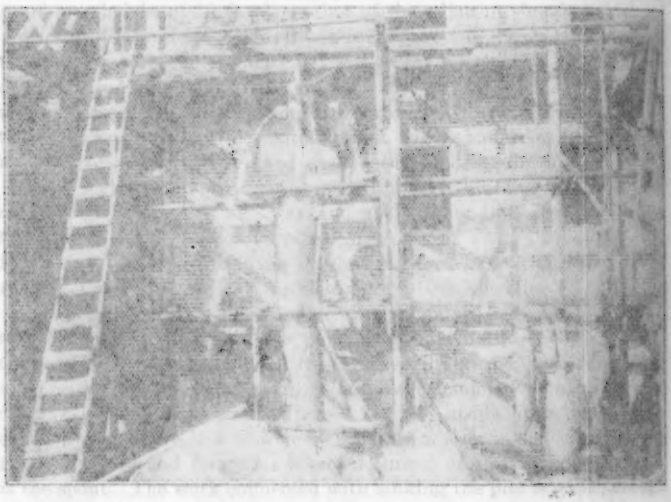

FIG. 24.—SAME PILE AS SHOWN IN FIG. 23, AFTER SINKING WAS COMPLETED.

FIG. 25.—CRACK IN WALL OF BUILDING CAUSED BY TENDENCY OF BLOCKING TO ROLL.

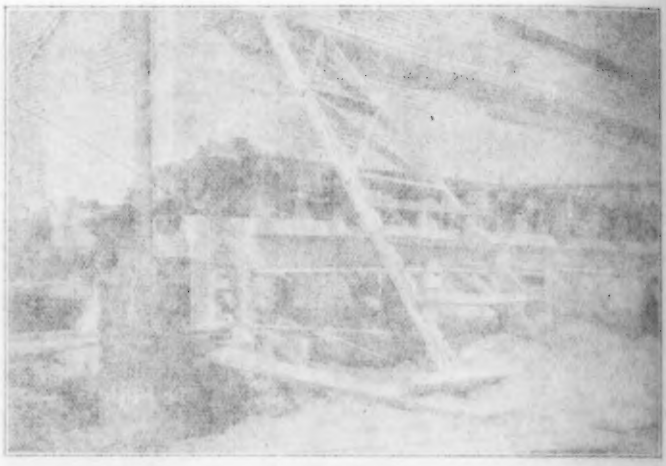

FIG. 22.—FRAME PILE AS SHOWN IN FIG. 23, AFTER DRIVING WAS COMPLETED.

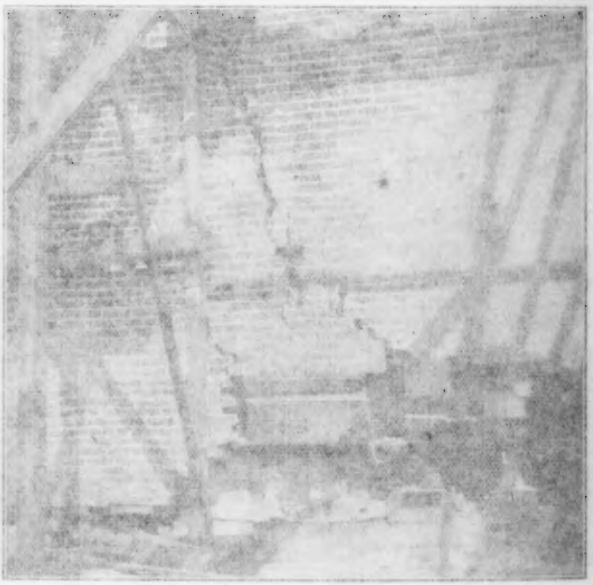

FIG. 23.—CRACK IN WALL OF BUILDING CAUSED BY TENDENCY OF BLOCKING TO HOLL.

Mr. Phillips.

Fig. 23 shows a pile which has reached a depth where skin friction offers too much resistance to be overcome by the weight of the pile alone, or even by a process which was called the "blow." This consisted in shutting off the water where it is seen escaping above and thus forcing it to find an outlet around the outside of the pile, thereby lessening the skin friction. When the "blow" was not effective, the pile, if on the outside of the building, was loaded as shown, and, if inside, was forced down with jack-screws.

Reinforcement may be used in such portions of the pile as may require it, but it was not necessary in the work described. In this work, 153 piles, ranging in diameter from 22½ to 30½ in. and in length from 108 to 112 ft., were sunk.

For the support of the walls of the main packing house, the piles were put down in pairs, each pair supporting a reinforced concrete beam which was to carry its share of the wall. When the piles required for the purpose were completed, and in advance of the completion of those intended to support the columns inside the building, the beams they were to support were poured, and in due time the weight of the walls was brought to a bearing on them.

Fig. 24 shows the same pile as Fig. 23, the sinking being completed. The lower end of this pile rests on cemented gravel, 116 ft. below the surface. The blocking and jack-screws show the method of holding up the brick walls while the foundation was sinking at the rate of 0.1 ft. per day. At the corner, inside the building, the mate of this pile has been sunk. A hole will be cut through the foundation, below the surface, and a reinforced concrete beam will be built on the two piles.

Fig. 25 shows one of several cracks in the walls of the building caused by the tendency of the blocking to roll. Such fractures had to be closed up after the building had been brought to a state of rest. After piers of brick set in cement mortar had been substituted for the wooden blocks and wedges, there was no further tendency to roll.

During the progress of the work this building had been sinking constantly, but at rates that varied according to the distance from one corner of the building on the end nearest the slough, which had remained stationary. When, finally, the walls were brought to rest on the new foundation, the subsidence at some points amounted to fully 2 ft.

The columns supporting the floors of the three departments of the main packing house were in three rows in each department. To carry these, two intermediate rows of piles were sunk in line with the original piers, and reinforced concrete beams resting on the intermediate piles carried the three columns in alignment with them.

The tank house, being a lighter structure, was handled in a different way. The concrete piles for it were set away from the old founda-

Mr. Phillips.

tion, and on these, continuous beams were poured. The building was moved over to the new foundation.

The work of erecting the buildings had progressed simultaneously with that of the new foundations. That it might be maintained in as nearly a level condition as possible, the walls and columns had been carried on jacks and oak wedges which were kept constantly adjusted. In spite of the care used to prevent it, the walls were badly cracked, and required considerable repairs.

There is no intention to convey the impression that there were no difficulties in sinking the piles, but such difficulties were readily overcome. It was seldom that a pile would follow the jetting as it proceeded. Instead, a cavity of some depth usually had to be washed out beneath, into which the pile would sink in due time. In general, the first 50 ft. or so of sinking was comparatively easy; but beyond that depth, in most cases, more or less urging had to be resorted to. If, however, larger piles had been necessary, or if a greater penetration had been required, or both, the work could still have been accomplished without undue difficulties.

Mr. Goodrich.

E. P. GOODRICH,* M. AM. SOC. C. E.—This paper appeals to the speaker more strongly with reference to incidental and exterior phenomena than with reference to the ingenious and eminently satisfactory method used in righting the elevator, which is the primary reason for the paper.

The first item of particular interest to the speaker is the demonstration that a structure of the size of this grain elevator, when built of reinforced concrete in accordance with the proper design, becomes a monolithic structure capable of being subjected to extraordinary stresses without seriously damaging the building. The settlement and righting of this elevator are almost identical with an experience concerning a grain elevator in Algiers, erected and righted by French engineers.

The moral of this story is an indirect demonstration of the need of caring for reverse moments in all bottoms, and at the points of intersection of bottoms and columns, together with the need for care in the design of columns to resist bending where need is shown. So long as reinforced concrete members were designed after the fashion of those made of timber or steel, difficulty was sure to arise, but, with the wider adoption of the cantilever, difficulties have disappeared and better structures been secured. The speaker has been interested in noting the widening use of the cantilever, even in steel and timber work, and believes that members thus designed are more efficient than almost any other device for the same purpose.

Reverting to the fact of the monolithic nature of large reinforced concrete structures, many instances may be cited of caissons designed

* New York City.

Mr. Goodrich.

for use as foundations for bridges, docks, etc., which have been handled, lifted on one side, tilted, and manipulated in almost any way found necessary without great difficulty.

The second point of interest refers to the earth pressure phenomena described. The wave that was thrust up, perhaps from some deep stratum, can be made the source of information with reference to earth pressure matters, which may prove of value through an analysis of its size, rate of formation, etc., if such data can be made available. For a long time the speaker has been advocating the making of careful explorations of sub-strata under large buildings, going down many feet below the customary foundation depth. Demonstrations of this need, in addition to that afforded by the Canadian Pacific grain elevator, were also mentioned by Robert B. Stanton, M. Am. Soc. C. E., in his discussion* on earth pressure formation in connection with a slide which took place on the Canadian Pacific Railroad within his observation.

The upheaval of the bottom of the Panama Canal is a gigantic demonstration of the same fact. On a much smaller scale, the upheaval of a steam shovel excavation in Cleveland, which occurred several years ago during the cutting through of a street, is pertinent.

It is the speaker's belief that properly made explorations and physical tests of the soil secured will make it possible to prophesy the possibilities of just such failures as occurred in connection with this grain elevator. Where such possibilities are indicated, obviously, engineers can take all needed precautions to prevent their occurrence. This belief has been applied by the speaker in several foundation investigations, and it is equally applicable to the analysis of soil conditions at Panama or Winnipeg. This paper is thus believed to be of wider interest than that covered in its main description of the mechanical methods used in combating the particular difficulty here encountered.

Paper No. 1364

INDUCED CURRENTS OF FLUIDS*

By F. zur Nedden, Esq.

With Discussion by Messrs. Clemens Herschel, Carl George de Laval, John C. Trautwine, Jr., and F. zur Nedden.

Synopsis.

The effects of internal and external friction on the movement of fluids can be traced in many instances to the induction of secondary currents which are co-existent with the main flow along geometric stream lines, and completely alter the resultant motion. The sources of the induced currents are the molecular forces at work in the marginal strata.

Induced Counter Currents.—These are generated when kinetic energy is transformed into pressure energy in diffusors.

The energy lost by the generation and maintenance of the counter currents is practically independent of the roughness of the wall.

Diffusors with geometrically similar cross-sections show a maximum of efficiency at a narrowly defined angle of dilatation. Actual figures are shown on Fig. 4. This angle increases slightly with increasing roughness and with increasing viscosity. It is no less harmful for the efficiency of the diffusor to have it opening out too quickly than to make it too slender. Spiral flow increases the efficiency of diffusors. The maximum of loss occurs, not at sudden enlargements, but in diffusors opening out at about 60 degrees.

* Presented at the meeting of October 20th, 1915.

Transverse Induced Currents.—These are generated where the direction of flow is altered, that is, in bends, elbows, etc. It is proved, both mathematically and by experiment, that their intensity depends in the first place on the ratio between radius of curvature and width of the vessel. (See Fig. 13.) This ratio is called degree of curvature. Two symmetrical transverse induced currents are generated in ordinary bends. The loss of head caused by their impact against each other—the restriction in free cross-section resulting from the transverse motion—and the loss of head due to repeated acceleration and retardation of every single vein of the current, are the three principal causes for the extra loss due to curvature. The roughness of the bend plays an unimportant part. The losses seem to be roughly proportional to the square of the speed. They are not confined to the bend proper. The readjustment to straight flow is usually connected with heavier loss than the adjustment to curved flow.

In Fig. 16 are tabulated the excess losses which must be expected to arise in American Standard long-turn elbows.

For speeds of flow above the critical limit, "equipotential" bends, shaped according to the classic conceptions of stream lines, cause a higher loss of head than simple circular bends of uniform rectangular cross-section.

Bends also cause a local decrease in static pressure (depression) which is often a multiple of their resistance. Fig. 18 gives an idea of the magnitude of these depressions as they occur in Standard elbows. Both losses and depression are more than doubled in **S**-pipes.

The following practical conclusions are derived from the foregoing facts:

Suction Pipes and Delivery Bends of Turbine Pumps.—The local depression caused by an elbow attached directly to the inlet of a low-lift pump can be detrimental to efficiency. At high rates of flow there is danger that gases may separate and interrupt continuity of flow if there are sharp turns in suction pipes.

When determining the efficiency of centrifugal pumps, care should be taken lest the gauge readings be influenced by the local depressions or excesses in pressure caused by bends. The use of decreasers for steadying the flow and removing local pressure differences is recommended.

Impellers.—The bearing which the induction of secondary currents may have on the transmission of energy in impellers cannot yet be defined.

The writer contends that it is possible to estimate the effects of the profile of the impeller on the distribution of pressure and velocity across the axial (longitudinal) section of the cells of the runner. The influence which the ratio of diameters must have on this distribution and on the efficiency and performance of the pumps is emphasized. As a means against the effects of excessive width of impellers the usefulness of radial guide-vanes at the entrance is questioned, and a suggestion is made for the introduction of an auxiliary partition of the cells and of a cylindrical guide in the entrance chamber. A modification of the usual application of velocity diagrams for determining the correct angle of the diffusor blades is recommended.

Diffusor Vanes.—Attention is drawn to Gibson's recommendations as regards proper curvature of diffusor vanes. The curvature of the axis of guide-channels is deemed advantageous. The dangers arising from a change in the sense of their curvature are emphasized.

Introductory.

Before entering into the subject, the writer wishes to state that this paper is directed more toward the practical consequences than toward an exhaustive treatment of the details connected with the induction of secondary hydraulic currents. Special reference is made to turbine pumps, but it is obvious that the results have just as important a bearing on the domains of water turbines, ship propellers, etc. As long as gases may reasonably be supposed to remain of constant density during their flow, the results are immediately applicable to fans, ventilators, turbo-blowers, etc.

There is a wide-spread misconception that, for all practical purposes, a sufficient insight into hydraulic phenomena may be gained by first applying the calculus to an ideal fluid free from internal or external friction and flowing along stream lines geometrically similar to the profile of the vessel, and then making good for the difference between the mathematical and the experimental results by introducing some simple coefficients covering the effect of friction. This mode of procedure would be perfectly admissible if the numerical quantities only of pressure and speed were affected by friction. This is not

the case. The effects of friction often cause the character of hydraulic phenomena to differ entirely from a flow along stream lines. Failure to realize this fact is mainly responsible for the frequent and gross discrepancies between practical and theoretical results of applied hydraulics. As an example, the writer would mention the conversion of kinetic energy into pressure by using diffusors, as compared with the reverse process in the nozzle.

Mathematics was able to throw considerable light on the reasons for these discrepancies. Investigations like those published by Navier, Stokes, and Boussinesq resulted in systems of fundamental equations which cover the influence of friction. Up to the present, however, the application of their equations to every-day practice has failed to crystallize into anything nearly as lucid as the application of the calculus to electrical phenomena. Even when based on the more complete equations of Navier, Stokes, and Boussinesq, hydraulic calculations do not reach the degree of approximation in predicting practical results of variations in design obtained by the laws of Ohm, Faraday, or Steinmetz.

In this plight designers are indebted to the hydraulic investigations, both mathematical and especially experimental, of the last 10 or 15 years for establishing a simplified and explicit new method of viewing and estimating the influence of certain typical changes in sectional area or direction of flow on the conversion of energy in hydraulic apparatus. The simplification consists in splitting up the complicated movements of the particles of non-ideal fluids into two components:

1.—A main movement along stream lines; and

2.—A secondary movement due to the influence of friction.

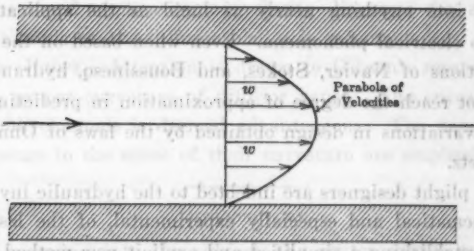
In other words, these investigations have established the fact that it is possible and admissible to look upon internal and external friction of non-ideal fluids as responsible for the induction of secondary currents, which, for convenience, will hereafter be referred to as induced currents.

The induced currents cause friction losses of their own, comparable to the phenomenon of self-induction of electric cables carrying alternating current. These additional and indirect losses could not be accounted for by a theory which considered one component only, namely, the main flow along geometrical stream lines.

The new development doubtless received its original impetus from Professor Osborne Reynolds'* discovery, in 1900, of turbulence in straight pipes. Professor Prandtl,† Chief of the Aero- and Hydrodynamical Laboratory at Goettingen, Germany, extended Reynolds' results to the flow in all kinds of pipes. Isaachsen,‡ who is manager and superintendent of a water turbine factory in Brunswick, Germany, was the first publicly to apply the new theory to the design of hydraulic machinery, especially water turbines.

I.—Induced Counter Currents.

1.—Critical Velocity.—All particles of a fluid flowing slowly through a straight pipe travel on straight lines (stream lines), according to a



DISTRIBUTION OF VELOCITY OF FLOW ACROSS THE CROSS-SECTION OF A PIPE AT A RATE OF FLOW BELOW THE CRITICAL LIMIT.

Fig. 1.

law which was experimentally found by Poiseuille§ and theoretically established by Hagenbach.‖ Those particles adjacent to the walls adhere to them, because the molecular forces of adhesion are stronger than the frictional (cohesive) forces between this, the marginal, and the next smaller concentric layer. The velocity is highest in the center and follows a parabolic law in decreasing to zero at the walls. (Fig. 1.) There is no relative movement between liquid particles and the wall. The resistance to flow is made up merely of the internal friction between the fluid particles (viscosity). The resistance is

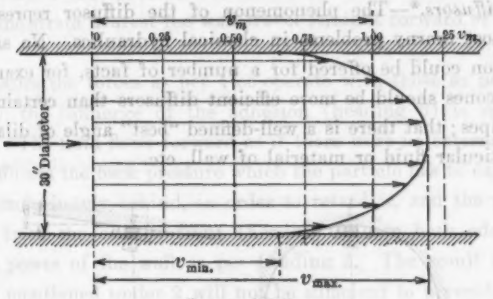
‖ Poggendorff's Annalen, 1860, I, p. 385.

independent of the roughness of the internal surface of the pipe. On this fact the working of viscometers is based.

When the rate of flow is increased beyond a certain "critical" speed, this ceases to hold true. The adhesive power of the wall is no longer strong enough to withstand the pull of the cohesive forces between the fluid particles. Consequently, the critical speed in every instance depends on the relation between the adhesive power of the wall (roughness and sectional circumference) and the viscosity of the fluid. Beyond the critical speed the strata immediately adjacent to the walls begin to move. The friction between them and the wall comes in as a



$v_{min.} = 0.57\ v_{max.}$
$v_m = 0.84\ v_{max.}$
$v_{max.} = 1.75\ v_{min.}$

DISTRIBUTION OF VELOCITY OF FLOW ACROSS THE CROSS-SECTION OF A PIPE ABOVE THE CRITICAL VELOCITY
(Mean Values of Results found by Williams, Hubbell, and Fenkell)

FIG. 2.

new source of losses. The velocity still is highest in the axis of the pipe, but the character of the flow has changed: the velocity follows an elliptical law in decreasing from the maximum in the center to a minimum at the wall.* (Fig. 2.) For water of 65 to 70° Fahr., this minimum is about 57% of the maximum.

The critical speed, for water of the same temperature and ordinary 4-in. iron pipe, is about 1 ft. per sec. In practically all technical instances the rate of flow is above the critical value.

2.—Nozzles.—It is well known† that all across the outlet of a smooth nozzle the velocity is so uniform, and so nearly $= \sqrt{2\,g\,H}$

* Williams, Hubbell and Fenkell, *Transactions*, Am. Soc. C. E., Vol. XLVII, p. 185.

† John R. Freeman, *Transactions*, Am. Soc. C. E., Vol. XXI, p. 365.

(where H is the combined velocity head and pressure, in feet, at the nozzle inlet) that the product of $\sqrt{2gH}$ and the area of the nozzle outlet can be taken to be a very accurate expression for the quantity of water passing through the nozzle per second. The explanation for this fact is that the particles deflected by the conical walls are continually getting into the way of those radially adjacent. By these impacts the latter convey as much energy (*vis viva*) to the former as is on the other side taken away from them by external friction. The influence of wall friction is thus automatically eliminated. The real flow comes remarkably near that of an ideal fluid.

*3.—Diffusors.**—The phenomenon of the diffusor represented one of the most thorny problems in classical hydraulics. No satisfactory explanation could be offered for a number of facts, for example: that straight cones should be more efficient diffusors than certain trumpet-shaped pipes; that there is a well-defined "best" angle of dilatation for each particular fluid or material of wall, etc.

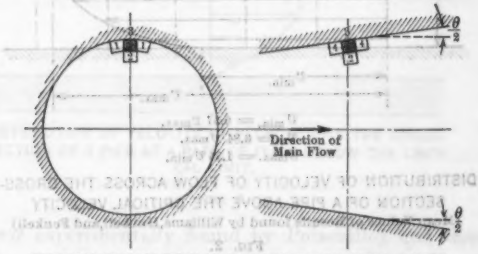


DIAGRAM OF MOLECULAR FORCES IN MARGINAL LAYER OF A DIFFUSOR

FIG. 3.

To get at the root of the problem, it is necessary to study the various molecular forces acting on a particle immediately adjacent to the wall. They can be described thus (Fig. 3):

1.—The forces of cohesion with the particles (1-1) tangentially adjacent on both sides. They pull in opposite directions and rectangular to the main flow (axis of diffusor). In straight, smooth pipes these forces are in equilibrium; their influence on the motion is zero.

* That is, increasers or pipes enlarging in cross-section: the reverse of a nozzle.

2.—The cohesion of the particle (2) radially adjacent and pulling in the direction of the main flow.

3.—The adhesion to the wall (3) pulling opposite to the direction of the main flow.

4.—The forces due to the inertia of the particles (4-4) immediately in front and immediately behind, when looking in the direction of the main flow.

When the fluid flows through a straight pipe at a constant rate, the result of the forces mentioned under 1 and 4 is zero, and the forces under 2 exceed (at speeds above the critical) those under 3. Consequently, the strata nearest the wall travel straight forward at a uniform speed.

In nozzles the forces as per 4 co-operate with those as per 2. Consequently, the influence of the adhesion (heading 3) is very nearly removed. The fluid flows forward as if there were no external friction.

In diffusors the back pressure which the particle has to exert against the one immediately behind, in order to retard it, and the pressure it receives from the one in front (heading 4), are both added to the adhesive power of the wall as per heading 3. The result is that the cohesion mentioned under 2 will not be sufficient to prevent the strata near the wall from reversing and flowing backward.

That this returning movement is not only limited to an infinitesimal layer near the walls, but that it permeates a considerable portion of the available cross-section may be made clear by an example chosen at random, say, a horizontal, conical increaser from 3 to 4 in. in diameter.

When 240 gal. per min. flow through such a diffusor, there will prevail a mean speed of about 11 ft. per sec. in the smaller and of about 6 ft. per sec. in the larger area. According to theory, the difference in pressure between the large and the small end should be $\frac{11^2 - 6^2}{2g} \cong 1.3$ ft. This formula neglects friction. In practice, the difference in a standard increaser will be about 1 ft., 0.3 ft. head being lost in the increaser.

The explanation for the excessive loss is found when taking into account, first, the influence of internal and external friction in the inlet pipe; and second, the same influences within the diffusor proper.

Turning to Fig. 2, it will be seen that the center vein of the stream flows at a rate of about 1.19 of the mean velocity, or at 13 ft. per sec.; the speed of those particles nearest the walls of the pipes will be about 0.57 of the maximum, or, in this instance, 7.4 ft. per sec. Even when not considering the friction within the diffusor itself, it is easy to show that a return current must necessarily be induced by this variation of the speed across the pipe section.

The velocity head of the center vein is: $\frac{13^2}{2\,g} \cong 2.6$ ft. As no energy is added during the flow through the diffusor, the velocity head at the outlet must be $2.6 - 1.0 = 1.6$ ft. (1 ft. being the increase in pressure observed), or the speed of this particular vein at the outlet will be $\sqrt{2\,g \times 1.6} \cong 10$ ft. per sec.

When singling out nearer the circumference another stream line entering with a speed of about 8.5 ft. per sec., we find that its velocity head is $\frac{8.5^2}{2\,g} = 1.11$ ft., which decreases by 1 ft., and therefore leaves only 0.11 ft. at the outlet, corresponding to a velocity of 2.7 ft. per sec. The area of this particular stream line would have to increase to about 3.15 times its original area $\left(\frac{8.5}{2.7}\right)$, whereas the rate of enlargement of the increaser is only about $\frac{4^2}{3^2}$, or 1.8. Particles entering with a velocity of about 8 ft. per sec. would arrive at the outlet with zero speed. The peripheral strata with speeds ranging from 8 ft. per sec. downward to 7.4 ft. will not be able to reach the outlet at all; they will, after exhausting their store of energy, reverse their direction and flow backward from the area of higher to that of lower pressure.

Considering now the effect of viscosity and adhesion in the diffusor proper, it is clear that in reality the individual veins of fluid cannot choose their way as independently as at first supposed. Returning particles will be reversed and re-accelerated by their friction against molecules moving at a greater speed. By this assistance they can overcome the friction with the pipe and the back pressure toward the inlet. The acceleration effected by the internal veins must be proportional to the area of contact between the respective strata, and proportional also to the viscosity.

The gradient of back pressure against which the fatigued particles have to be forced is a direct function of the angle of dilatation or

divergence, θ (Fig. 3). It is obvious that there will be one definite limiting value of θ for every fluid. Below this value, the external friction will exceed the viscous forces, and stop the counter currents. It follows, further, that this angle will be greater, the more viscous the fluid, and smaller, the smoother the inner surface of the pipe.

Under all circumstances, there will be a complicated exchange of energy between the different strata. This explains the excessive hydraulic loss connected with the transformation of kinetic energy into pressure.

The first to investigate more closely the extent (though not the exact nature) of these losses were Francis* and Fliegner.† With their results the engineering world rested content until at the beginning of this century the exigencies of turbine pump design pressed for a more intimate knowledge. Among the various investigations dealing with the subject those of Andres‡ and Gibson§ are the most noteworthy.

These scientists clearly realized the fact that the loss of head in divergent pipes is the result of two distinct components: the losses due to the primary or inductive and those due to the induced or secondary currents. Andres succeeded in separating these components. By combining the results of Andres with those of Gibson and several other independent investigators, the writer arrived at a graphical diagram, Fig. 4.

If the mean velocity $\left(v = \frac{9}{f}\right)$ of the water flowing through the throat of the diffusor be v_1 ft. per sec., and v_2 that prevailing in a certain enlarged cross-section, then, according to Bernoulli's theorem, there should be an increase in pressure between the two points of:

$$\Delta h = \frac{v_1^2 - v_2^2}{2g} \text{ (feet)} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

If the increase is found in reality to be only $\Delta h'$, then the total loss of transformation $= V_d = \Delta h - \Delta h'$, and the "efficiency of the diffusor", as a percentage of Δh, can be expressed thus:

$$\eta_d = 100 \frac{\Delta h'}{\Delta h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

* Lowell Hydraulic Experiments, New York, 1871, p. 219.

† *Zivilingenieur*, 1875, p. 97.

‡ "Versuche über die Umsetzung von Wassergeschwindigkeit in Druck", Forschungsarbeiten des Vereines Deutscher Ingenieure, Heft 76.

§ "Loss of Head Through the Flow of Water Through Divergent Pipes", *Proceedings*, Royal Society, London, Vol. 83, 1910; and *Engineering*, February 16th, 1912.

If V_d is expressed as a certain percentage of Δh, and, in this shape, is called V_d', then:

$$V_d' = 1 - \eta_d \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

It is possible to integrate for each particular diffusor, the loss in head,

$$h_r = \int d\, h_r \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

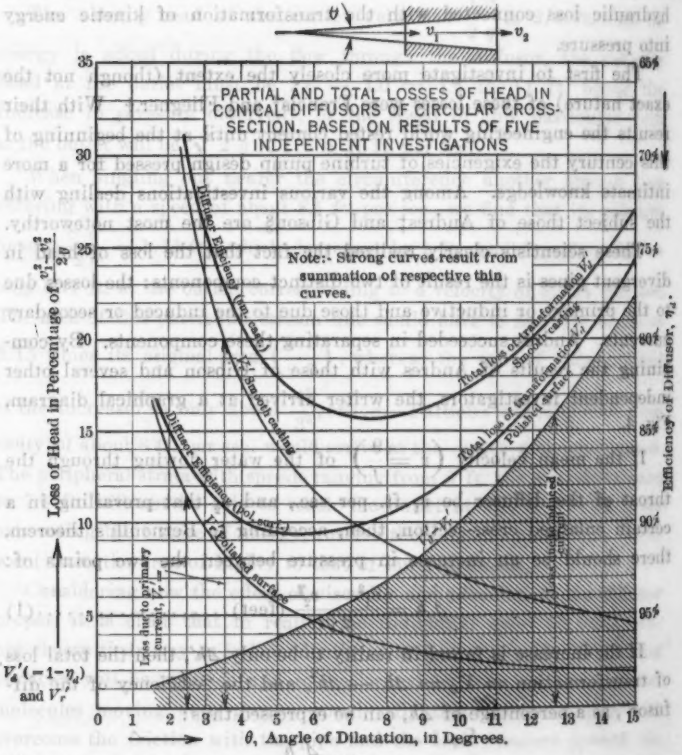

FIG. 4.

which would occur if each differential section of the increaser were part of a pipe of uniform cross-section, that is, if the peculiar additional loss resulting from the transformation of kinetic energy into pressure were non-existent. h_r, which may be called the loss due to the primary

current, can again be expressed as a percentage, V_r' of the theoretical increase in pressure:

$$V_r' = \frac{100\, h_r}{\Delta h} \qquad (5)$$

$V_r' =$ infinity where $\Delta h = 0$, that is, in straight pipes of uniform cross-section with angle of dilatation $\theta = 0$. $V_r' = 0$ when $h_r = 0$, that is, when the length of the diffusor $= 0$, $\theta = 180$ degrees. This is the case of sudden enlargement.

Between these two extremes the value of V_r' depends on roughness, width (hydraulic radius), etc., in true proportion with the ordinary coefficients of friction in pipes. V_r' is represented in Fig. 4 by the faint hyperbolic curves.

When subtracting the wall friction loss, V_r', from the values experimentally established for the total loss of head, V_d', we find the remainder, $V_d' - V_r'$, or "enlargement loss", due to the loss caused by the secondary or induced currents.

If the new theory is right, then this enlargement loss must be independent of the roughness of the walls, and merely a function of the viscosity and the angle of dilatation, θ. As the several hundreds of experiments on which Fig. 4 is based were all carried out with water at temperatures of about 60 to 70° Fahr., that is, of equal viscosity, subtraction of the wall friction losses from the total losses must lead to practically the same values, whether the diffusors were rough or smooth. This tallies with a remarkable degree of exactitude: This is shown by the curve for $V_d' - V_r'$, marked by hatching in Fig. 4.

Fig. 4 is of considerable interest to the designer of diffusors. It emphasizes most forcibly two important facts:

1.—The degree of polish given to the walls of a diffusor is not of paramount importance—provided only that the angle of dilatation is right: the best diffusor efficiency obtainable by an unmachined though smoothly cast taper pipe is about 84%, and a high polish, under the best conditions, can only add another 6% in the efficiency of the diffusor. On the other hand, a polished diffusor diverging at an angle of 14° is less efficient than an unmachined increaser of 8° divergence.

2.—It is just as harmful to the diffusor efficiency to have a diffusor opening out too quickly as to make it too slender. Though, for example, the best results are obtained with an unmachined taper pipe diverging at 8°, 10% of diffusor efficiency is lost by designing

the angle, θ, either 3 or 14½ degrees. Generally, the designer will be much more tempted to choose a large angle of dilatation than a small one, as the latter implies a great axial length of the apparatus.

It is interesting to note, and quite consistent with the theory of induced hydraulic currents, that the diffusor losses, V_d', reach a maximum of more than 100%, not at 180° of dilatation, but at about 60°, and then fall slowly to about 100% at 180 degrees.* At angles larger than 60° obviously the counter currents find an area large enough to develop freely and without materially disturbing the main flow. As the difference, $\frac{v_1^2 - v_2^2}{2g}$ (see Equation (1)), is, in these instances, entirely used up for overcoming the local counter currents, there remains no back pressure which would reverse the flow near the farther end of the diffusor.

It is also consistent with the new theory that the experiments prove rectangular cross-sections to cause a greater loss in head than circular ones. Evidently, in the corners of the rectangles, counter currents can develop more freely.

Perhaps the strongest proof for the thesis that the induced currents are to blame for the inferior efficiency of diffusors is to be found in the fact that the efficiency of one and the same diffusor improves when these currents are artificially hampered, and that it reaches almost 100% when the diffusor is forcibly swept clean from any secondary currents. This can be done by imparting to the fluid a rotary motion around the axis of the diffusor. The centrifugal forces thus developed overcome the molecular resistances of wall friction and inertia, and create a resultant nearly parallel to the wall. The phenomenon then closely resembles in effect the flow through a nozzle.

This proof was elegantly furnished by Andres. The water before entering his experimental diffusors had to pass either:

a.—Twenty strainers of fine-meshed wire gauze, securing an absolutely parallel flow of the individual stream lines; or,

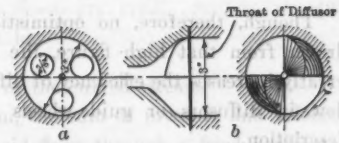
b.—One such strainer; or,

c.—Nothing; or,

d.—A blind flange, 3 in. in diameter, with three equidistant round holes, each ⅞ in. in diameter—(Fig. 5*a*) an arrangement called an "eddying sheet"; or,

* *Engineering*, February 16th, 1912, Fig. 1, p. 205.

e.—A "propeller sheet", that is, a piece of sheet iron cut along two rectangular diameters and then having two opposing quadrants bent open, thus giving the stream lines a twist (Fig. 5*b*).



"EDDY SHEET" (*a*) AND "PROPELLER SHEET" (*b*), AS USED BY ANDRES

FIG. 5.

Andres read the pressures in the throat, that is, after the liquid had passed the respective strainers or sheets, and at the end of the diffusor. Table 1 contains his results.

TABLE 1.—PERCENTAGE OF EFFICIENCY OF TRANSFORMATION OF KINETIC INTO PRESSURE ENERGY.

Diffusor.	Polished Castings.					Smooth castings unmachined.
	20 strainers.	1 strainer.	Nothing (normal).	"Eddy sheet."	"Propeller sheet."	
Circular cross-section. $\theta = 8°20'$.....	86.5	87.1	88.3	92.5	98.9	85.4
Rectangular (pyramidal) diffusor.....	67.0	66.5	71.9	73.2	70.6	....

The increase of efficiency effected by introducing a spiral flow is very striking. With reference to the high figure, 98.9%, obtained by using the "propeller sheet" in connection with the conical diffusor, the experimenter says:

"Though this figure is based on readings made with every conceivable care (as are all the others), doubts must be expressed as to its correctness. The loss due to the primary current alone must be about 4 per cent. [See Fig. 4.]

"The apparent inconsistency is removed by considering that the calculation of η_d is based on a value of the velocity, v_1, in the throat, which itself is found by dividing the quantity per second through the cross-section of the throat. This would involve that the stream lines be parallel to the axis, which they, of course, are not. The actual mean velocity is bound to be higher and therefore the value of

$$\Delta h = \frac{v_1^2 - v_2^2}{2g}$$

greater.

"However, it is impossible even to guess at the approximate value of the tangential components which should be geometrically added to the calculated mean velocity."

Though, therefore, no optimistic practical conclusions should be drawn from that high figure, the fact remains that the spiral flow greatly increases the efficiency of diffusors. As will be shown later, the flow in diffusors or guide-wheels of centrifugal pumps is of this description.

II.—Transverse Induced Currents.

Transverse induced currents, namely, currents circulating in a direction rectangular to the axis of the primary or inductive current, occur wherever the direction of flow is altered. The most notable example is the bend or elbow. The channels between two successive blades in the runner of a turbine or a turbo-pump or turbo-compressor represent bends curved in two planes. The induced currents resulting from this complicated curvature have an important bearing on the design of these machines.

Before entering into the discussion of experimental results, it is essential to make a short mathematical survey of the ground to be covered.

1.—The "Law of the Rotating Water".—If an ideal fluid flows through a circular bend of rectangular cross-section, then, according to Isaachsen's investigations,* the velocities of the stream lines are inversely proportional to their radii of curvature. If r_a and r_i represent the outer and the inner radius, respectively, and w_a and w_i the corresponding velocities at these radii (Fig. 6), the following equation holds good:

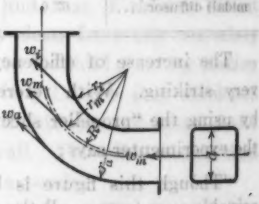


Fig. 6.

$$\frac{w_a}{w_i} = \frac{r_i}{r_a} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

or,

$$w_a\, r_a = w_i\, r_i = w_m\, r_m = C \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

The constant, C, is found by determining the radius, r_m, where, according to this result, a velocity, w_m, must occur, which is equal to the mean velocity $\left(w = \frac{9}{f}\right)$ in a straight channel of identical cross-

* *Zivilingenieur*, 1894-96.

section. This radius was called by Pfarr* the "neutral radius", and works out of the equation:

$$r_m = \frac{d}{\text{nat. log.} \frac{r_a}{r_i}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

where $d = r_a - r_i$ = radial width of the curved stream.

According to Bernoulli's theorem, the sum of pressure and velocity head remains constant when the fluid flows through a fixed horizontal channel.

The pressure must be lowest where the radius is smallest, and it is particularly noteworthy that, at the smallest radius, the pressure must be expected to be lower than at the neutral radius, that is, lower than in the straight ducts leading to and fro. The difference of the inside and outside pressure should be in feet:

$$\Delta p = \frac{w_i^2 - w_a^2}{2g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

w_i and w_a follow from Equations (7) and (8).

The minimum pressure in the bend should then be lower than the pressure in the adjacent straight portions of the channel by:

$$\Delta p' = \frac{w_i^2 - w_m^2}{2g} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

where again w_i and w_m follow from Equations (7) and (8).

It should be emphasized again that this "law of the rotating water" was originally developed for ideal fluids. Without modification, it must be applied only to conditions of flow which agree in character with those of an ideal fluid, for example, flow below the critical velocity. Obviously, it is possible to apply it to a marginal layer, all particles of which flow forward in the same direction with a uniform speed. As this application furnishes the basis for the explanation of the origin and intensity of transverse induced currents, the writer felt encouraged to follow up the consequences of Equations (6) and (9) a little farther. He found a new law which is remarkably well substantiated by the experimental facts:

When calling "degree of curvature" the ratio, $\frac{R}{d}$ (where R is the radius of the geometrical axis, and d is the radial width (diameter) of the bend), this new law can be expressed thus:

* "Die Turbinen", 1st ed., p. 77; 2d ed., p. 86.

The total pressure difference, Δp, and the maximum depression, $\Delta p'$, are constant for a constant degree of curvature and constant mean velocity of flow. They are direct functions neither of the width of the bend nor of the radius of curvature.

Proof.—If $\frac{R}{d} = \text{const.}$, then

$$d = \frac{1}{\text{const.}} \times R = k \times R.$$

k is the reciprocal of the degree of curvature.

Now

$$r_i = R - \frac{k \times R}{2} \quad \ldots\ldots(11a)$$

and

$$r_a = R + \frac{k \times R}{2} \quad \ldots\ldots(11b)$$

Equation (7) leads to:

$$w_i = \frac{w_m \times r_m}{r_i} \quad \ldots\ldots(12a)$$

$$w_a = \frac{w_m \times r_m}{r_a} \quad \ldots\ldots(12b)$$

With these expressions, Equation (9) assumes the shape:

$$\Delta p = \frac{w_i^2 - w_a^2}{2g} = \left[\left(\frac{w_m r_m}{r_i}\right)^2 - \left(\frac{w_m r_m}{r_a}\right)^2\right] \frac{1}{2g}$$

$$= \frac{w_m^2}{2g} \times r_m^2 \left(\frac{1}{r_i^2} - \frac{1}{r_a^2}\right) \quad \ldots\ldots(13)$$

By introducing $k = \frac{d}{R}$ and the value for r_m as per Equation (8), a rather formidable looking equation is derived:

$$\Delta p = \frac{w_m^2}{2g} \times \left[\frac{\dfrac{R\,k}{R + \dfrac{k\,R}{2}}}{\text{nat. log.} \dfrac{R + \dfrac{k\,R}{2}}{R - \dfrac{k\,R}{2}}}\right]^2 \times \left[\left(\frac{1}{R - \dfrac{k\,R}{2}}\right)^2 - \left(\frac{1}{R + \dfrac{k\,R}{2}}\right)^2\right] = \frac{w_m^2}{2g} \times R^2 \left(\frac{k}{\text{nat. log.} \dfrac{1 + \dfrac{k}{2}}{1 - \dfrac{k}{2}}}\right)^2$$

$$\times \frac{1}{R^2} \left[\left(\frac{1}{1 - \dfrac{k}{2}}\right)^2 - \left(\frac{1}{1 + \dfrac{k}{2}}\right)^2\right] \quad \ldots\ldots(14)$$

In this equation, R^2 cancels.

Therefore:

$$\Delta p = \frac{w_m^2}{2g}\left(\frac{k}{\text{nat. log.}\dfrac{1+\frac{k}{2}}{1-\frac{k}{2}}}\right)^2 \times \left(\frac{1}{\left(1-\frac{k}{2}\right)^2} - \frac{1}{\left(1+\frac{k}{2}\right)^2}\right) \quad \ldots (15)$$

In the same way, an expression is found for the maximum depression:

$$\Delta p' = \frac{w_m^2}{2g}\left[\left(\frac{k}{1-\frac{k}{2}} \times \frac{1}{\text{nat. log.}\dfrac{1+\frac{k}{2}}{1-\frac{k}{2}}}\right)^2 - 1\right] \quad \ldots\ldots (16)$$

Both Δp and $\Delta p'$ are, therefore, quite independent of R or d.

Only the degree of curvature, $\frac{R}{d}$, or its reciprocal, k, and the mean velocity of flow determine the range of secondary pressures formed in the marginal layers of a bend.

These formulas may be applied only as long as the fluid may be supposed actually to follow the inner curvature of the walls; that is, only as long as the bend is not too sharp. They do not, as a rule, apply to short-turn elbows or tees. Professor Pfarr's experiments, published by Dr. Lell,* prove the law to be still applicable when $k = 1$. $k \leqq 1.2$ should represent the upper limit.

2.—Induced Currents in Bends (Long-Turn Elbows).—We now enter into a general survey of the conditions which develop when a non-ideal fluid enters a bend. Fig. 2 shows that in a straight pipe the central vein flows about 75% faster than the particles at the wall. When entering a bend, the molecules in the center will develop the strongest centrifugal force $\left(\frac{m w^2}{R}\right.$ being proportional to the square of $\left.w\right)$, or, in other words, will have a greater inertia to keep them flowing in the same direction and not be deviated before meeting strong resistance. They will dislodge the particles in their way, which, in turn, must find a way to flow toward the center of curvature. By thus following a curved path of smaller radius, they, in turn, gain in centrifugal force, while the dislodging particles travel on curved paths of larger radius and gradually lose energy. A moment later, therefore, dis-

* This is shown later.

lodgers and dislodged ones change their rôles and swing back. These oscillations are very distinctly visible in Fig. 12.*

The path of any single particle is approximately spiral, that is, it is the result of the co-operation of a main forward flow and a rectangular component: the circular or transverse induced current.

The pressure, of course, varies in accordance, being highest where the retardation of particles is strongest, and *vice versa*. Fig. 7 is a diagram based on experimental results as found by Dr. von Cordier.†

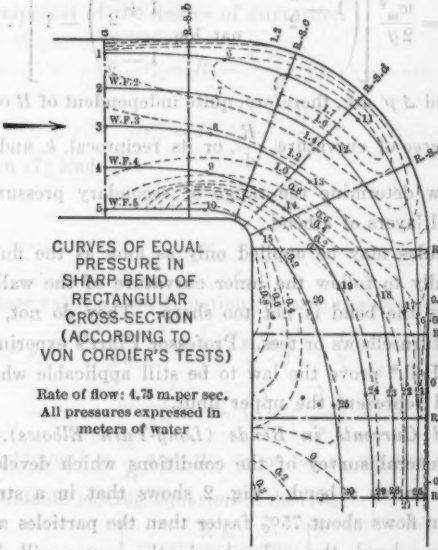

FIG. 7.

It shows clearly an elevation of pressure of 1.7 m. (about 5½ ft.) on the outer wall at Radial Section *d* (*R. S. d*) and the corresponding depression of minus 0.8 m. (or 2½ ft.) on the inner side

* Gardner S. Williams, M. Am. Soc. C. E., has kindly drawn the writer's attention to a very distinct exhibition of these oscillations in the tests made by Messrs. Williams, Hubbell, and Fenkell, at Detroit in 1901 and 1902. Referring to *Transactions*, Am. Soc. C. E., Vol. XLVII, April, 1902, p. 152, there will be noted in Fig. 77 a plotting of gauge readings taken at two extremities of the horizontal diameter of a 16-in. pipe, which is indicated on p. 149 of that paper. These observations were taken 213 ft. down stream from the termination of the first 90° bend at Cavalry Avenue and Porter Street, which had a radius of 5 ft. It will be noted that the maximum pressure varied from side to side as the velocities changed.

† "Strömungsuntersuchungen an einem Rohrkrümmer," ed. by Oldenbourg, Munich, 1910.

between Radial Sections f and g. The water arriving from "up hill" then by its impetus increases the pressure at the inner side. At *R. S.* i, the pressure has already increased again to 0.3 m., or 1 ft. above zero. The depletion of the outer strata of the bend, meanwhile, has caused the pressure there to fall from 5½ ft. above to about 4 in. (— 0.1 m.) below zero. (These fluctuations continue far into the straight duct following the bend. The process and the losses resulting therefrom are not at all confined to the bend proper. This fact makes the determination of what should be termed "loss due to curvature" a very difficult matter.)

It should be emphasized that the experimental bend used by von Cordier really was a short-turn elbow, with the coefficient, $k \cong 1.4$. The pressure difference created by it, therefore, cannot be expected to tally with the result of Equation (15).

This and other reasons caused Professor Pfarr, of water turbine fame, to start a thorough investigation of the flow through bends. A very extensive series of tests was carried out under his supervision, and after Pfarr's recent death, published* by Dr. Lell of the Darmstadt Technical University, Germany. These tests will rank forever among the classical feats of experimental engineering. It is impossible to go into any details of these remarkable investigations, as they fill a voluminous report. An impression of the thoroughness of the work performed may be gained from Fig. 13 of Lell's paper.† Water flowed from a tank, through a perfectly level and smooth rectangular duct, into the experimental bend ($k = 1.0$) which could be covered with interchangeable plates of various materials. The pressures were measured by several hundred stand-pipes, and connected by pipes of special design to rows of small borings at the inner and outer curved wall and on both covers of the bend. The walls of the straight ducts leading to and away from the experimental bend were also equipped with rows of test borings. Further, by introducing Pitot tubes of special design, the pressures within any stratum could be measured at any desired point with a very high degree of exactitude. The most elaborate precautions were taken against any errors, the readings being checked and

* "Beitrag zur Kenntnis der Sekundärströmungen in gekrümmten Kanälen," *Zeitschrift f. d. ges. Turbinen Wesen*, 1914, Nos. 9, 19, 20, 21.

† It is regretted that it has been impossible to secure, for reproduction in this paper, copies of the photographs used in illustrating Dr. Lell's paper.

rechecked. The difference of friction caused by a surface having hundreds of small openings as compared with a smooth surface also was carefully tested. It was found, in the arrangement tested, to be negligible. It is needless to state that all refinements of up-to-date scientific investigation were scrupulously applied.

In addition to the measurements, experiments were carried out with a glass cover-plate.

Air was introduced through special borings under a slight pressure. This method furnished an excellent means of studying the currents in detail. Photographs also were taken of these air-streams, and clearly show the deviation of the stream lines from the concentric shape assumed by the theory of stream lines.

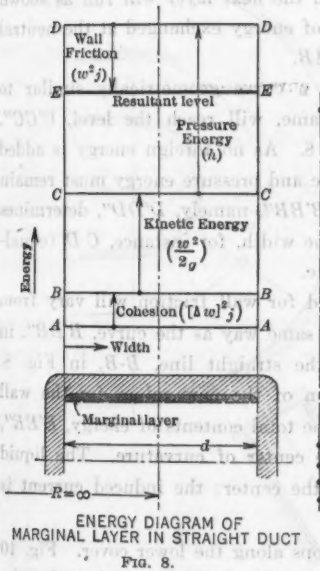
These experiments revealed the formation of two symmetric induced currents. As this result represents the foremost point gained in the knowledge of induced currents of fluids, it should be described here a little more in detail. The foregoing reasoning with regard to the struggle between dislodging and dislodged particles can only serve to convey a general idea of the nature of the phenomenon. It really leaves unanswered the crucial questions: Do the particles simply whirl around in an irregular manner? Is the way by which they travel from one side of the pipe across to the other dependent merely on accidental influences which we may never hope to disentangle? Or, do the dislodged particles travel along certain well-defined, typical paths, thus replenishing the inner strata in a methodical manner and forming a stream which may justly be termed an induced current? And, if so, where does that current start, and why must it be reproduced in every case?

In answering these questions the writer wishes to emphasize that the following considerations were not the base but the outcome of the experiments.

It was found that the induced currents originate in the strata nearest the covers and gradually increase in volume and intensity while the main current flows forward. When considering a very thin marginal layer along the upper or lower cover of the bend, the friction against the outer or inner curved wall may reasonably be disregarded. At the entrance to the bend all particles of this layer travel forward in about the same direction, and with reasonably the same

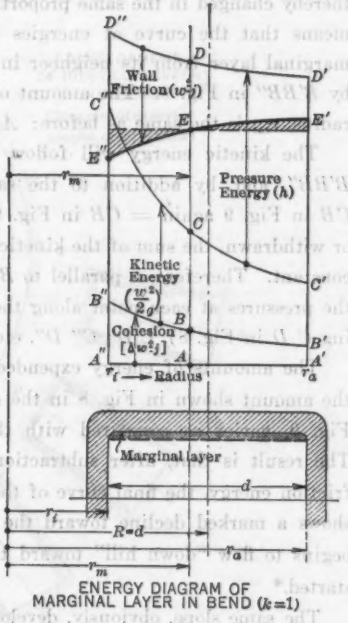
speed. The conditions on which the law of the rotating water is based exist with great approximation for this layer.

Referring to the foregoing survey for the various molecular forces pulling or pushing at each particle, the writer developed an energy diagram (Fig. 8), for the marginal layer under consideration. As long as the fluid flows through a straight duct or pipe (Fig. 8), each particle of the marginal layer receives, through the adhesive forces of



ENERGY DIAGRAM OF MARGINAL LAYER IN STRAIGHT DUCT

FIG. 8.



ENERGY DIAGRAM OF MARGINAL LAYER IN BEND ($k=1$)

FIG. 9.

the next layer, an amount of energy corresponding to, say, A-B; for the particles of that new layer also all flow forward with a uniform speed which, however, is slightly higher. Each particle of the marginal layer represents, by virtue of its velocity, a velocity head or kinetic energy of $\frac{w^2}{2g} = BC$, and, by virtue of its pressure, the potential energy, CD. It spends, in the form of wall friction, an amount of energy, DE.

As all particles of each of the two layers travel with uniform speed, the energy lines, *B-B*, *C-C*, *D-D*, and particularly the resultant, *E-E*, are level: The contents of the layer under consideration has no tendency to flow either to the right or to the left, but straight on.

As soon as the layer enters the curved part of the pipe, the velocities change in accordance with the law of the rotating water. The absolute differences in speed along the width of two adjacent liquid layers are thereby changed in the same proportion as the speeds themselves. This means that the curve of energies conveyed to each particle of the marginal layer from its neighbor in the next layer will run as shown by *B'BB''* in Fig. 9. The amount of energy exchanged at the neutral radius, r_m, is the same as before: *AB*.

The kinetic energy will follow a curve geometrically similar to *B'BB''*, and, by addition to the same, will reach the level, *C'CC''*. *CB* in Fig. 9 again = *CB* in Fig. 8. As no foreign energy is added or withdrawn, the sum of the kinetic and pressure energy must remain constant. Therefore, a parallel to *B'BB''*, namely, *D'DD''*, determines the pressures at each point along the width, for instance, *C D* (equaling *C D* in Fig. 8), *C'D'*, *C'' D''*, etc.

The amounts of energy expended for wall friction will vary from the amount shown in Fig. 8 in the same way as the curve, *B'BB''*, in Fig. 9, varies as compared with the straight line, *B-B*, in Fig. 8. The result is that, after subtraction of the new values for the wall friction energy, the final curve of the total contents of energy, *E'EE''*, shows a marked decline toward the center of curvature. The liquid begins to flow "down hill" toward the center: the induced current is started.*

The same slope, obviously, develops along the lower cover. Fig. 10 is a descriptive diagram reproducing the indications given by the streamlets of air bubbles pressed into Pfarr's experimental bend. The rectangles shown are the cross-sections of the bend along the indicated radii, and turned by 90° into the drawing plane. Immediately

* Strictly speaking, the assumption of separate layers of flow is not absolutely in harmony with the conception of viscosity, as defined by Newton, nor with the characteristics of a turbulent movement, as established by Professor Reynolds. Still, this simplification is highly serviceable, and it is admissible as long as it does not contradict experimental evidence, but only serves to illuminate it. It is to be borne in mind, however, that no conclusions must be drawn from the assumption of flow in layers, unless they are corroborated by experiment.

after the fluid has entered the bend the situation is shown by the diagram marked 1. The two layers next to the covers show a distinct component of flow, as indicated by the arrows. A moment later, the particles contained in the original layer, by their momentum and owing to the general outward tendency of the flow of the contents, travel downward and upward along the inner vertical wall, as shown by 2.

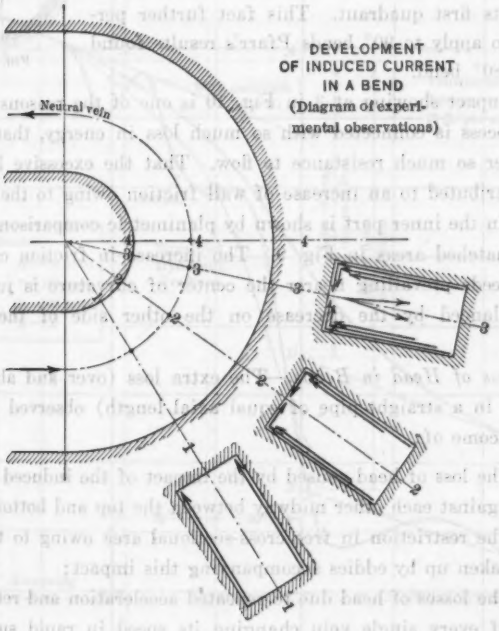


FIG. 10.

New layers come into contact with the upper and lower cover-plates and follow the paths taken by the first layers. At the same time, by the radial movement of all these particles, a radial pull is exerted on the next inner strata indicated in the diagram at 2 by the shorter horizontal arrows. Soon the state of affairs suggested at 3 is reached. The streams meet with considerable impetus half way between the upper and lower cover.

It is easy to show that, in a bend of circular cross-section, this impact will not be less hard: Fig. 11.*

After a 90° curvature has been traveled, the induced current is well under way. Nothing new in principle happens, nor do the radial components materially increase in strength. This explains the fact, already observed by Weisbach, that the extra resistance caused by a circular pipe or coil does not exceed that of its first quadrant. This fact further permits us to apply to 90° bends Pfarr's results found with a 180° bend.

FIG. 11.

The impact showing at 3 in Fig. 10 is one of the reasons why the whole process is connected with so much loss in energy, that is, why bends offer so much resistance to flow. That the excessive loss must not be attributed to an increase of wall friction owing to the increase in speed in the inner part is shown by planimetric comparison between the two hatched areas in Fig. 9. The increase in friction caused by higher speeds prevailing nearer the center of curvature is just about counterbalanced by the decrease on the other side of the neutral vein (*E*).

3.—Loss of Head in Bends.—The extra loss (over and above that occurring in a straight pipe of equal axial length) observed in bends is the outcome of:

1.—The loss of head caused by the impact of the induced currents against each other midway between the top and bottom;

2.—The restriction in free cross-sectional area owing to the space taken up by eddies accompanying this impact;

3.—The losses of head due to repeated acceleration and retardation of every single vein changing its speed in rapid succession.

The preponderance of these losses which are due to imperfect exchange of molecular energies, indicates that the roughness of the walls can only have a very subordinate influence on the resistance due

* Indeed, the impact should be expected to be even harder in a circular cross-section. In a rectangular cross-section the vertical strata along the inner wall are passive, and form a baffle for particles which are pressed down or up by the forces developing in the upper or lower marginal layer. In a circular cross-section, however, fresh impetus is added to the induced currents on their whole way until they reach the point of smallest radius, which coincides with the point where the two currents clash against each other.

to curvature. This important fact is substantially shown by experiments to which the writer will presently refer in detail.

The last source of losses is the most prominent of the three and is most vividly accentuated in the diagram, Fig. 12.

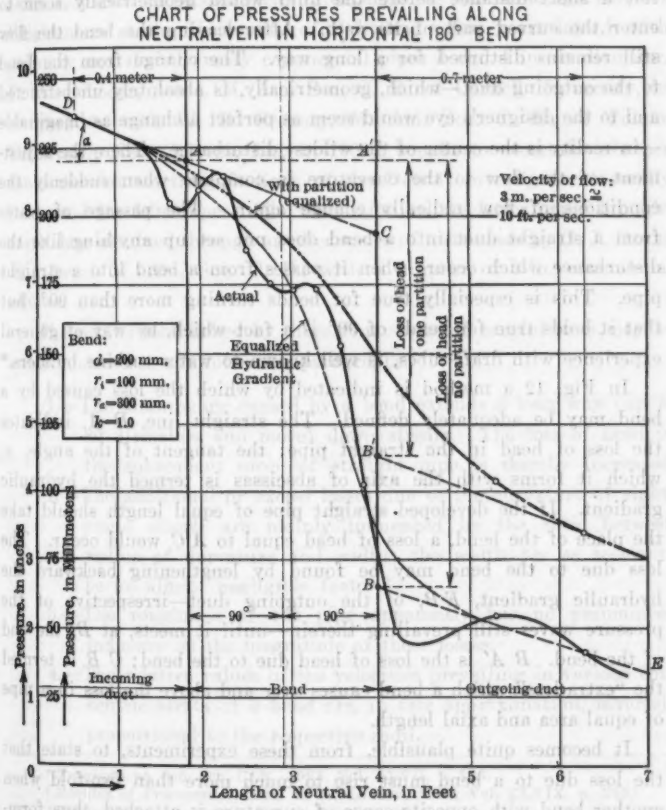

FIG. 12.

Dr. Lell measured the pressures prevailing all along the calculated "neutral vein" of Pfarr's experimental bend, and plotted them as ordinates over the development of the neutral vein as axis of abscissas. Fig. 12 represents his results for one speed, namely, 10 ft. per sec. The plottings for 20 and 30 ft. per sec. are very nearly identical with

this one, if their scales are reduced to $\frac{1}{4}$ and $\frac{1}{9}$, respectively. It follows that the total loss of head due to a bend should be expected to be pretty nearly in proportion to the square of the speed of flow.

Fig. 12 shows that the influence of the bend is already making itself felt a short distance before the fluid would geometrically seem to enter the curved part of its path. After leaving the bend the flow still remains disturbed for a long way. The change from the bend to the outgoing duct—which, geometrically, is absolutely unobstructed and to the designer's eye would seem as perfect a change as imaginable—in reality is the center of the wildest disturbance. There the adjustment of the flow to the curvature is complete when suddenly the conditions of flow radically change again. The passage of water from a straight duct into a bend does not set up anything like the disturbance which occurs when it passes from a bend into a straight pipe. This is especially true for bends turning more than 90°, but that it holds true for bends of 90° is a fact which, by way of general experience with draft-tubes, is well known to water turbine builders.*

In Fig. 12 a method is indicated by which the loss caused by a bend may be adequately defined. The straight line, $D\ A$, indicates the loss of head in the straight pipe; the tangent of the angle, α, which it forms with the axis of abscissas is termed the hydraulic gradient. If the developed straight pipe of equal length should take the place of the bend, a loss of head equal to $A'C$ would occur. The loss due to the bend may be found by lengthening backward the hydraulic gradient, $E\,B$, of the outgoing duct—irrespective of the pressure waves still prevailing therein—until it meets, at B, the end of the bend. $B\ A'$ is the loss of head due to the bend; $C\ B$ is termed the "extra-loss" which a bend causes over and above the loss in a pipe of equal area and axial length.

It becomes quite plausible, from these experiments, to state that the loss due to a bend must rise to much more than two-fold when another bend with opposite sense of curvature is attached, thus forming an **S**. The same will hold true as regards the lowest local depression occurring in an **S**.

a.—Loss in Bends of Circular Cross-Section.—It is interesting to compare the results thus far obtained with the conclusions arrived

* See also the experiments by Messrs. Williams, Hubbell, and Fenkell.

at by a number of investigators, both in the United States and abroad. Messrs. Williams, Hubbell, and Fenkell, at the beginning of this century, carried out a series of very careful tests with large bends (12 to 30 in. in diameter) forming part of the water supply system of Detroit, Mich.* A second series of experiments was made by Professor Brightmore, at the University of Calcutta, a few years later,† with ordinary and slightly rusty commercial pipes 3 and 4 in. in diameter. E. W. Schoder, Assoc. M. Am. Soc. C. E., of Cornell University, in co-operation with W. B. Gregory, M. Am. Soc. C. E., of Tulane University, New Orleans, La., in 1909,‡ sought to ascertain whether the somewhat startling findings of the Detroit investigators actually held good for 6-in. pipes. The discussion on the latter paper brought forth data obtained through another series of tests made by G. J. Davis, Jr., Assoc. M. Am. Soc. C. E., with a number of 2-in. commercial elbows.

The results established by these four series of careful tests may be compounded into the following paragraphs:

1.—The disturbance caused by a bend extends a long way (up to 80 diameters and more) down stream. The loss of head in the subsequent piece of straight pipe is thereby increased.

2.—The additional or excess losses due to the curvature of right-angle elbows are mainly influenced by the ratio between radius of curvature and width; the width *per se* seems to be an almost negligible factor.§

3.—The roughness of the pipe apparently has no pronounced influence on the magnitude of these losses.

4.—The relative values of the velocities prevailing in various concentric strata of a bend are, in fair approximation, inversely proportional to the respective radii.

§ It may not be out of place to refer to Weisbach's classical formula for the resistance to flow by a bend, namely:

$$H_f = \left[0.13 + 0.16 \left(\frac{d}{R}\right)^{3.5}\right] \frac{w^2}{2g}.$$

Though, by the foregoing tests, the coefficients of this formula are shown to be inaccurate, its structure indicates that Weisbach was well aware of the paramount importance of the ratio, $\frac{d}{R}$.

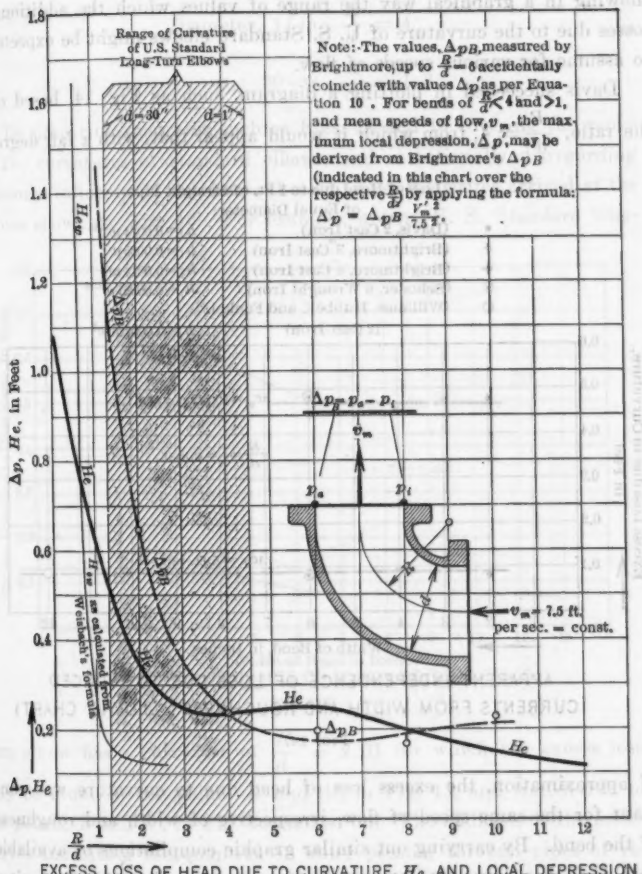
Neither of these investigators apparently knew of Isaachsen's and Pfarr's theories, and the latter's experiments were made at a later date than theirs. The coincidence of the results, therefore, is very convincing proof of their correctness.

The American and English investigations amplify the German results in one important direction. They furnish an experimental basis for the variation of the loss in function of $\frac{R}{d}$. Fig. 13, which is mainly plotted from Brightmore's results, reveals the fact that this function is rather complicated. When the Detroit experimenters first established a branch of the H_e-curve, Fig. 13, they viewed the results with considerable doubt. They themselves considered it rather queer that the losses should have a pronounced minimum for $\frac{R}{d} \sim 3$ and a secondary maximum at $\frac{R}{d} \sim 6$.

Their findings, however, were corroborated by all subsequent investigators, Brightmore arriving at his results apparently without knowing of theirs.

When comparing this curve with the results obtained from diffusors at various angles of dilatation, the similarity in character is most suggestive. The explanation should lie in the fact that in both cases the additional losses, being mainly due to induced currents, must diminish or grow in proportion to the possibility of these induced currents developing more or less freely. The influences producing the induced currents and governing their effects were shown to be manifold. It is quite conceivable that as one or the other of these influences (impact between adjacent particles, restriction in free area by eddies, repeated acceleration and retardation of every single particle) assumes a more or less prominent rôle, secondary maxima and minima of the total resultant loss should be formed.

To try to make any more definite statements would be rash, in face of the scant experimental evidence at hand; still, as this evidence covers a range of widths from 2 to 30 in., of ratios, $\frac{R}{d}$, from less than unity to 20, speeds from 1 to 10 ft. per sec., and degrees of roughness varying from smooth brass, through galvanized iron, to rusty cast iron, a network of interpolation can be thrown over the ground covered

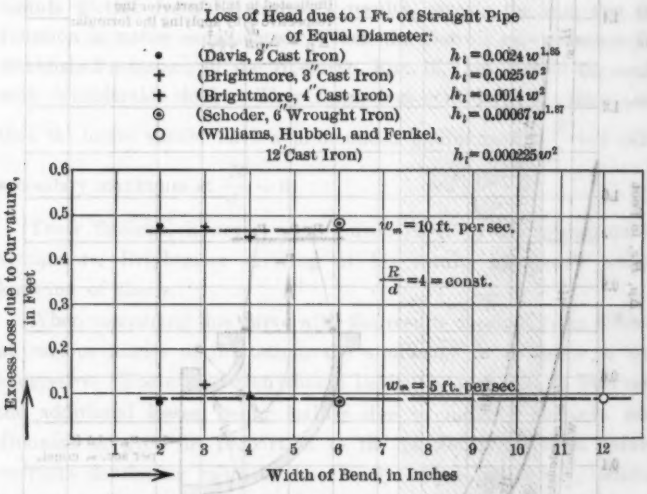


EXCESS LOSS OF HEAD DUE TO CURVATURE, H_e, AND LOCAL DEPRESSION AT OUTLET, Δp_B, AS MEASURED BY BRIGHTMORE ON 3 IN. AND 4-IN., RUSTY, COMMERCIAL ELBOWS, IN FUNCTION OF THEIR DEGREE OF CURVATURE, $\frac{R}{d}$.

FIG. 13.

by experiments. An effort was made by the writer by this means to put into the hands of the engineer a small comprehensive chart showing in a graphical way the range of values which the additional losses due to the curvature of U. S. Standard elbows might be expected to assume for various speeds of flow.

Davis succeeded in plotting a diagram, such as Fig. 14, based on the ratio, $\frac{R}{d} = 4$, from which it would appear that, with a fair degree



APPARENT INDEPENDENCE OF LOSS DUE TO INDUCED CURRENTS FROM WIDTH AND ROUGHNESS (G.J.DAVIS' CHART)

FIG. 14.

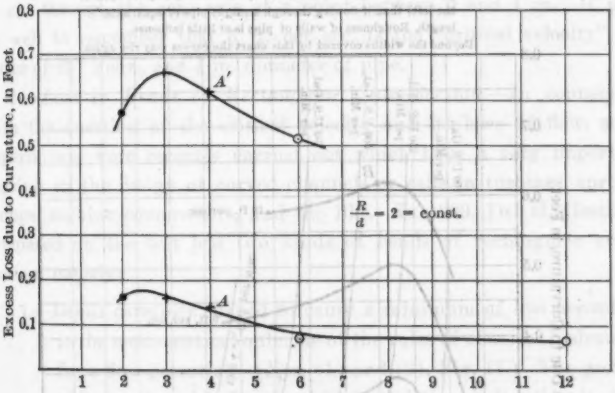
of approximation, the excess loss of head due to curvature was constant for the same speed of flow, irrespective of width and roughness of the bend. By carrying out similar graphic compilations of available data for other degrees of curvature (for example, Fig. 15), the writer became aware of the probability that this may not be a general rule. The variations of loss with increasing width, as emphasized by Fig. 15, naturally must be smallest for the ratio, $\frac{R}{d} = 4$, because there the total losses are a minimum.

The curvature of U. S. Standard elbows changes with the width. It is smooth for small, and rather abrupt for large, widths of pipe:

Diameter, $1\frac{1}{4}$ in., $\frac{R}{d} = 4$;

" 30 " $\frac{R}{d} = 1.8$.

By preparing diagrams such as Figs. 14 and 15 covering the range of the curvatures of standard elbows, and intentionally disregarding whatever influence of roughness there may be, the writer arrived at the values shown by Fig. 16. For example, a 4-in. U. S. Standard long-



SPECIMEN OF CHARTS ON WHICH FIG. 19 IS BASED

FIG. 15.

turn elbow has a curvature of $\frac{R}{d} = 2.01$ for which the excess loss may be found at the points, A and A', in Fig. 15, and transferred to the points, B and B', in Fig. 16, and so on. The addition of the cross-curves indicating the quantity of water passing through pipes of respective width at the given speeds might help to make the diagram handier for practical use.

Fig. 16 might also, without risk of great errors, be used in connection with 1912 Standard elbows as indicated, for their curvatures do not differ very much from those of the former and are smoother throughout.

The values, as plotted in Fig. 16, should be regarded as preliminary approximations, though based on a great number of very careful tests under actual conditions of use. It should be noted that the exact

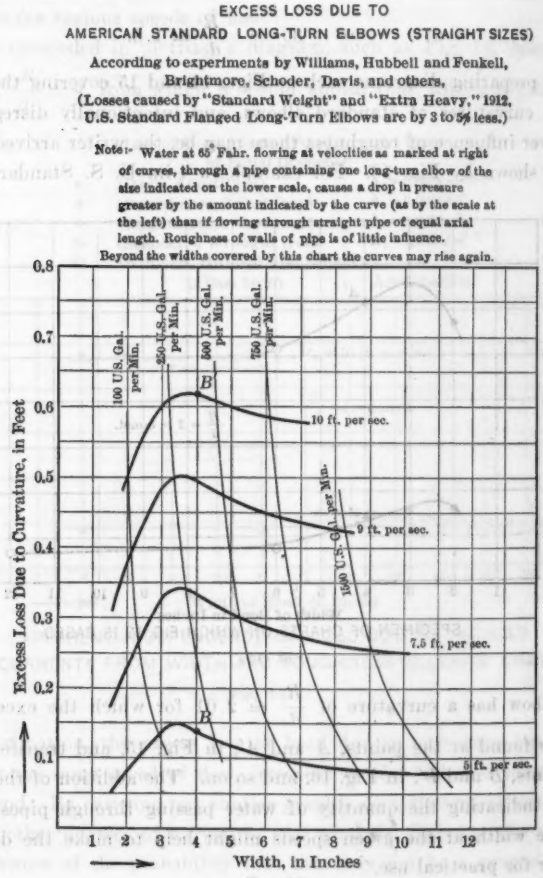


FIG. 16.

influence of roughness is by no means cleared up, and, when once definitely known, may alter somewhat the curves of Fig. 16, though the writer believes that their possible inaccuracy will by no means

be such as to endanger their usefulness seriously. The writer, in plotting these curves, believed that even approximate values would be more welcome than the present state of absolute uncertainty as regards these losses. It should be emphasized that the curves only hold good for water of ordinary temperature; further, that due provision (of about + 10%) should be made for the unavoidable inaccuracies in fitting pipes together at the joints. If the cross-section of an elbow is diminished by sediment, the actual speed of flow through the reduced area must be calculated and Fig. 16 consulted for the loss of head occurring at that speed.

It will be noted that the 5 ft. per sec. loss curve seems to tend to cut through the zero axis at a point between 0 and 1 in. It may be well to remember that 5 ft. per sec. is the "critical velocity" for water of 65° Fahr., and $\frac{3}{4}$ in. diameter of pipe.

b.—Loss in Bends of Rectangular Cross-Section.—In connection with the question of the critical velocity and its laws of flow, some experiments were recently carried out which have a very important bearing on the design of curved channels or cells in turbines, turbine pumps, turbine compressors, and the like. In 1909, Dr. H. Grether* compared on the test bed two kinds of bends of rectangular cross-section, namely:

1.—Bends carefully shaped to cause a minimum of loss according to the mathematical outcome of the rules of classical hydraulics for a flow-potential. (Nos. (1) and (2), Fig. 17.) The profiles given to these bends are equipotential hyperbolas, that is, they follow stream lines which according to theory the particles of an ideal fluid would describe when flowing at constant pressure and velocity around a corner.

2.—Simple bends of uniform cross-section forming a circular arc.

The expectation that the equipotential bends would cause the least drop in pressure of the compared variations of shape was fully realized as long as the speeds of flow remained below the critical limit. This was proved by using a viscous oil as a flowing medium.

As soon, however, as water was used for testing, and the critical speed was far exceeded, the results were a complete reversal of the first:

* "Ueber Potentialbewegung tropfbarer. Flüssigkeiten in gekrümmten Kanälen," Berlin, 1909 (Simion's Verlag).

For speeds of flow above the critical limit the equipotential bend caused the highest resistance to flow.

It is impossible, even roughly, to outline in this paper the ingenious details of Grether's remarkable investigations.

The writer only wants to emphasize, that if designers of hydraulic machinery would train their instinct for the correct shapes of blades or profiles by mere geometrical considerations, they would arrive at conclusions which are diametrically opposite to practical experience.

Parenthetically it might be remarked that, according to Grether's results, bends of rectangular cross-section offer a lesser resistance if—*ceteris paribus*—the cross-sectional rectangle stands on its small face (Nos. (3) and (4), Fig. 17) than if it lies on its broad side.

4.—Local Diminution of Pressure in Bends.

a.—Rectangular Cross-Section.—Pfarr used his experimental bend $\left(\frac{R}{d} = 1\right)$ for investigating the extent to which Equations (9) and (10) could be used for practical calculations. For this purpose, he measured at all speeds the minimum pressure at the inner wall. This generally occurred at a radius which was inclined against the entrance radius by about 50 degrees. He also measured the maximum pressure prevailing in the same radial cross-section. Table 2 is an extract from his data.

TABLE 2.—Comparison of Calculated and Measured Pressure Differences Forming at the Inner and Outer Wall of a Bend Having $\frac{R}{d} = 1$. (Denominations as per Equation (9).)

Calculated.				Measured.
v_m, in feet per second.	v_i, in feet per second.	v_a, in feet per second.	Δp, in feet.	Δp, in feet.
9.82	17.9	5.96	4.125	4.26
18.03	35.8	11.92	17.67	17.20
27.45	53.7	17.88	39.90	39.45

The two last columns tally remarkably well.

In addition, Dr. Lell corroborated these findings by a series of special tests which verified the expectation that the maximum and minimum pressures on the two walls (though by no means the pressure diagrams across any one radial cross-section) did, under all cir-

cumstances, coincide very satisfactorily with the results derived from the law of rotating water.

b.—Circular Cross-Section.—It is highly gratifying that Professor Brightmore took a similar series of pressure readings when testing ordinary commercial elbows of 3 and 4 in. diameter. His gauges were fixed to the outermost and innermost points of the outlet of the elbow, as indicated on Fig. 13, which also shows the differences between their readings.

This fact may be explained broadly by the following consideration: although the individual stream lines do not even nearly coincide with the circular shape on which the foregoing formulas are based, there must be some spot—provided only that the bend be long enough—where particles follow, for a short space, the curvature of the inner radius. At this particular place the minimum pressure and maximum velocity will coincide with the mathematical value found. The same applies to the wall having the largest radius. At least at one place on the inner and at one place on the outer wall of the channel will the pressures and velocities prevail, which follow from Equations (6) and (9). This is important. For instance: Gases will separate from a liquid flowing through a curved suction pipe, no matter whether the depression prevails only in one particular small area or on the whole inner wall of the bend. The continuity of flow is thereby interrupted. The variation between the actual flow and the idealized mathematical diagram of the flow, in this instance, is of minor importance, as far as the practical consequences of the depression go. Again, the violence of the transverse currents depends merely on the amount of the pressure difference, Δp, not on its local extent.

Brightmore found that these differences were independent of the roughness and—within his experimental limits—of the width of the elbow. Degree of curvature and speed of flow were the only two decisive influences found to bear on the depression.

As the points of measurement, especially the inner one, do not coincide with the area where, according to Pfarr's tests, the full maximum difference of pressure prevails, Brightmore's findings must not be expected to tally with the results calculated from Equation (9). By checking them against Equations (9) and (10) the writer found that they fairly coincide, between $\frac{R}{d} = 1$ and $\frac{R}{d} = 4$, with the results of

Equation (10), that is, that Brightmore's gauge differences may be taken to represent the maximum depression below the pressure of the ingoing straight pipe. He feels encouraged to believe that, by an accident, the pressure at the inner gauge point was by so much higher than the minimum p_i (which, for these degrees of curvature, occurs somewhat before the outlet) as the pressure, p_a, exceeds the value, p_m. This, by the way, is not much, in any case. In the face of the remarkable coincidence of measurement and calculation, as proved by Pfarr and Lell, the data established by Brightmore would, in the writer's opinion, only tend to corroborate the thesis: that in elbows of circular cross-section, too, the maximum and minimum values of pressure, with a fair degree of approximation, may be calculated from Equations (9) and (10). For example: According to Equation (8), in a bend having $\frac{R}{d} = 2$, $d = 4$ in. diameter, $R = 8$ in., the "neutral" radius, r_m, would be:

$$r_m = \frac{4}{\text{nat. log. } \frac{10}{6}} = \frac{4}{0.511} = 7.8 \text{ in.}$$

Then, according to Equation (7), at a mean speed, $w_m = 7.5$ ft. per sec.:

$$w_i = \frac{7.5 \times 7.8}{6} = 9.75$$

$$w_a = \frac{7.5 \times 7.8}{10} = 5.85.$$

Equation (9) would indicate the maximum pressure difference, Δp, to be:

$$\Delta p = \frac{w_i^2 - w_a^2}{2g} \sim 0.95 \text{ ft.}$$

Equation (10) would furnish the lowest depression below the pressure in the ingoing straight pipe:

$$\Delta p' = \frac{w_i^2 - w_m^2}{2g} = 0.61 \text{ ft.}$$

The pressure difference read from the gauges by Professor Brightmore was:

$$\Delta p_B = 0.64 \text{ ft.} \quad \text{(See Fig. 13.)}$$

The fact that, for curvatures smoother than $\frac{R}{d} \sim 4$, Brightmore's figures show a rising tendency is, in the writer's opinion, due to the

circumstance that the position of the actual minimum pressure, p_i, shifts more and more toward the point where his instruments were fixed, namely, immediately in the outlet cross-section. This would mean that, for $\frac{R}{d} < 4$, he measured a difference of pressure smaller than Δp, and, for $\frac{R}{d} \sim 10$, he measured the full amount, Δp, as defined by Equation (10). Indeed, the value of Δp_B found by Brightmore for $\frac{R}{d} \sim 10$, namely, about 0.22 ft., tallies tolerably well with—and even exceeds—the value, Δp, as calculated from Equation (9), namely, 0.19 ft.

It can be taken as granted beyond dispute that depressions as indicated by Equation (10) (in combination with Equations (7) and (8)) do actually occur. It matters little at present whether they are 20% larger or smaller than the results derived from Equation (9). What does matter is that depressions are formed which are a multiple in many cases (and especially in standard elbows of large diameter) of the loss of head caused by the elbow. In order to supply the designer of pipe lines and hydraulic machinery with a handy means of estimating what depressions, $\Delta p'$, and maximum differences of pressure, Δp, must be expected, the writer has developed from Equation (10) the diagram, Fig. 18, which speaks for itself. It is again based on the curvatures of U. S. Standard long-turn elbows. As only the ratio, $\frac{R}{d}$, matters (besides the speed of flow), a second scale for the abscissas was added, having reference to 1912, U. S. Standard long-turn elbows. When comparing both abscissas it is evident that the slightly greater smoothness in curvature which was introduced with the 1912 Standards serves to diminish considerably the dangerous depressions which form in the elbow.

It is almost needless to emphasize the fact that short-turn elbows and T-pieces must cause very much more severe depressions. Therefore, they should never be allowed in suction pipes for great suction heads and high rates of flow.

III.—Some Special Practical Results.

No changes in the direction, and no retardation, of flow are possible without the generation of induced currents. They influence the flow

CALCULATED DEPRESSIONS, $\Delta p'$, AND MAXIMUM PRESSURE DIFFERENCES, Δp, AS BY FORMULAS (9) AND (10) FOR U.S. STANDARD LONG-TURN ELBOWS.

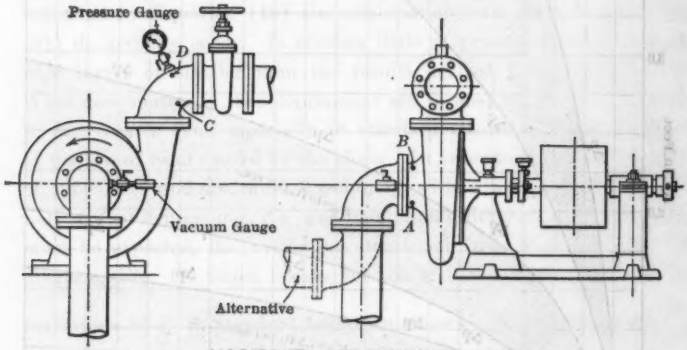
FIG. 18.

of fluids in such a way that in no case does the path on which the drops travel coincide with assumed "stream lines". The water flows through turbines and pumps on complicated spiral paths. The idea that the designer may be able to "guide" the water must at least be very considerably modified.

From the hurricane to the aeroplane propeller, and from the problems of the ship's screw to those of centrifugal pumps, induced currents are of paramount importance. Only a few examples can be singled out. These have been selected from the field of centrifugal pumps, with which the writer is specially familiar.

1.—Suction Pipes and Delivery Bends of Turbine Pumps.—Fig. 19 shows a typical arrangement of a horizontal centrifugal pump. For



HORIZONTAL CENTRIFUGAL PUMP

FIG. 19.

an example an 8-in. pump is chosen from the catalogue of a well-known American firm. This pump has a circular inlet opening of 10 in. and an "economic capacity" of 2 200 gal. per min. The mean speed of flow in the elbow that connects the suction pipe to the pump is about 9.1 ft. per sec. when pumping at that rate. For a slight overload capacity of 10% (2 430 gal. per min.) the speed of flow would be exactly $w_m = 10$ ft. per sec.

From Brightmore's experiments it is known that then the pressure at the point, A, Fig. 19, is lower than that prevailing at B by $\Delta p_B = \Delta p'$. The value of $\Delta p'$ is found, from Fig. 18, to be, for a 10-in. U. S. Standard long-turn elbow at $w_m = 10$ ft. per sec.:

$$\Delta p_B = \Delta p' = 1.65 \text{ ft.}$$

The actual depression, Δp_a, at the point, A, below the pressure of the "neutral vein", may then be estimated by applying the ratio:

$$\Delta p_a = \Delta p_B \frac{\Delta p'}{\Delta p}.$$

With $\Delta p \sim 2.35$ ft. (Fig. 18), $\Delta p_a \sim 1.15$ ft. The impeller, by its rotation, increases the pressure of each particle flowing into it by the same amount, say, for example, 20 ft., independent of the absolute pressure at which the particle enters. Around the circumference of the impeller the pressure varies by the same amount as across the entrance section. The violent mixing process occurring in the volute chamber equalizes these differences mostly at the expense of the higher local pressures. The result of the depression, Δp_a, therefore, is an all-round reduction in efficient pressure by about ~ 1 ft., or, in this instance, 5% of the total head.

If the last part of the suction pipe could be made straight, instead of an elbow, a marked increase in efficiency would result, especially if the suction pipe line were made 12 in. in diameter and connected to the pump by a straight reducer, which would straighten out all irregularities of flow. If, on the other hand, the alternative, as shown by dotted lines on Fig. 19, should have to be chosen, the **S**-pipe might be the cause of some trouble. The maximum depression, occurring somewhere near the point, A, would then be more than twice $\Delta p'$. At 30% overload capacity, which is no rare occurrence with pumps of that kind when pumping against a variable head, the speed of flow would be 13 ft. per sec., and that depression about 7 ft. or more. When the pump sucks about 20 ft. high, which in itself is no excessive suction head, the absolute pressure which remains to press the water into the impeller will only be: Atmosphere ($\sim$ 33 ft.) minus 27 ft. minus loss of head in suction pipe and strainer, that is, less than 6 ft., perhaps only 3 ft. Even if this remainder of pressure is sufficient to overcome the resistance when entering the impeller, air or vapors are sure to separate, and, owing to the great chemical affinity to iron of oxygen *in statu nascendi*, rapidly wear out the impeller. The pump, at the same time, works noisily and irregularly. The blame will be laid to the pump, but really the **S** in the pipe line is the cause of all the trouble.

In case trouble arises from the decrease in head or efficiency owing to the effect of the elbow leading into the pump, a smart representative

of the pump manufacturer might easily prove that "nothing is wrong with the pump" by fixing a pressure gauge at the point, D (Fig. 19), and a vacuum gauge midway between A and B. The latter will then indicate approximately the real mean entrance pressure (pressure of "neutral vein"), while the pressure gauge reads too high by the amount, $\Delta p - \Delta p'$. Taking, again, 2 430 gal. per min. as the rate of flow, then $w_m \cong 15.5$ ft., and, by aid of Fig. 18, or Equations (9) and (10):

$$\Delta p - \Delta p' \cong 1.9 \text{ ft.}$$

for an 8-in. Standard elbow. If the total head is low, the capacity large, and the elbows sharp, the importance of such an error is obvious. Either several gauges should be fixed all around the delivery orifice or the reading should be taken on a straight pipe after the water has passed a straight reducer, making allowance, of course, for the increase in velocity head entailed thereby.

2.—Impellers.—Closed impellers consist of a number of cells formed by the profiles of the impeller and by the back of one and the front of the next following blade. They are curved in two planes: first in the plane which contains the axis of the pump (curvature of profile); secondly in the plane rectangular to the former (curvature of blades).

When trying to apply the results gained from stationary bends to the cells of impellers, insuperable difficulties arise. These are specially great with reference to the curvature of the blades. In addition to internal and external friction of the fluid, three components of force are acting: one due to the centrifugal force of rotation, one due to the acceleration of the fluid relative to the impeller, and one due to the acceleration of Coriolis, that is, supplementary acceleration due to composite motion. It seems improbable that, within the near future, a clear and simple mathematical expression could be found covering the effect of the co-operation of these five component forces. To be of immediate practical use, the mathematical treatment would have to be simple enough to be applicable economically in the designing office of a factory. This possibility seems to be very remote.

The only benefit which designers may reasonably hope to derive from such mathematical and experimental research work is a development of a sound judgment for the constructive shapes necessary to produce or avoid certain effects. After all, this is the principal

basis of all industrial production of machinery: an engineering instinct based on the results of engineering science or physics.

When looking for such benefits, the application of the knowledge of induced currents to the curvature of profile is bearing some important fruits. The component forces due to rotation and to the acceleration of Coriolis are negligible around the eye or hub, especially where it is well machined. Within the cells proper their action is confined principally to planes parallel to the profile, and, therefore, should not be of very considerable influence on the diagram of pressures along the axial plane. The effects of the curvature of profile, therefore, may well be expected to be similar to those produced by the fluid streaming at an equal relative velocity through the stationary cell. The writer contends that, whatever the indirect effects of the two other components of external forces may be, the cause responsible for the "law of the rotating water", that is, the inertia of the relative flow, does not disappear. Its effect must be discernible in the final diagram of energy at the circumference of the impeller.

As the conclusions which the writer reaches on this base are verified throughout by practical experience, he ventures to outline them here in the hope that discussion may help to bring forth all available evidence of experiment and experience, either to support or to refute his contentions.

Fig. 20 represents a comparison of two extreme types of impellers. Each has the same axial length over all (l). The free entrance areas of the impellers (D'_1 diameter) and the individual cells shall be equal in both instances, also the angle, β_2, between the blades and the periphery, and the free discharge areas at that spot. The axial width, b_2, at the periphery, consequently, must be inversely proportional to the diameters, D_2. If the same quantity is delivered by each impeller, the radial components of relative speed, v (that is, those lying in the drafting plane), are equal throughout. The left-hand impeller is a typical low-lift, the right-hand one is a high-lift runner. If both rotate at an identical number of revolutions per minute, then the total heads generated are, in a rough approximation, proportional to the square of the diameter, D_2. The same holds good for the static pressures, *H st.*, prevailing at the circumference, which constitute an equal percentage of the total head in both cases, as the angles, β_2, are the same. Now, the differences in pressure, owing to the law of

rotating water, must influence the disposition of the peripheral pressure across the width of the impeller in the manner indicated by the curves, A' B' and A'' B''.

The ratio between width of cell and radius of curvature of the profile automatically turns out more favorable with the high-lift impeller. Furthermore, in a high-lift runner, the profile usually runs straight for a considerable distance before reaching the periphery. Both advantages result in the difference, $H_{max.} - H_{min.}$, being much

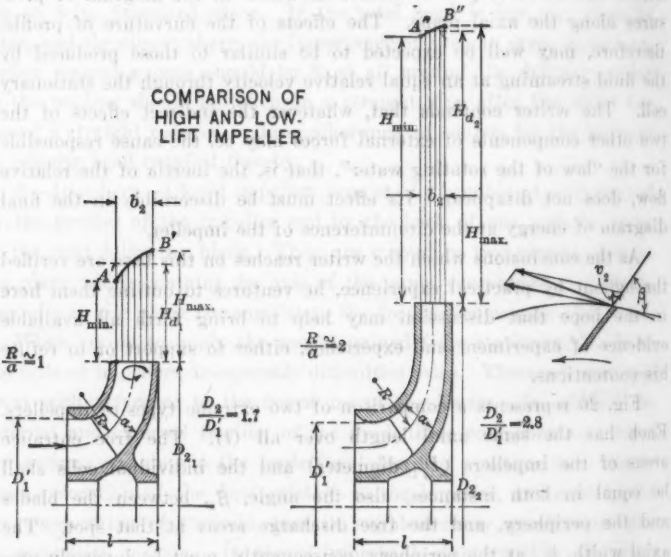


FIG. 20.

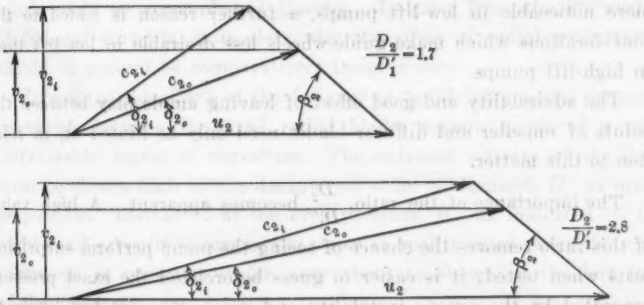
smaller absolutely in high-lift impellers. Relatively, the comparison is still more in favor of the high-lift runner. In Fig. 20, $H_{d_1} : H_{d_2} \cong D_{2_1}^2 : D_{2_2}^2$, consequently, an induced current of considerable energy, as characterized by the arrow, must influence, and in extreme cases even jeopardize, the generation of useful pressure in the low-lift impeller, though in high-lift impellers this influence is generally negligible.

A secondary consequence is a difference of pressure in the left-hand and right-hand clearance spaces at the periphery, which adds to the axial thrust an unknown quantity. This component of the axial

thrust does not vary with the head, but evidently with the square of the relative velocity, that is, of the delivery, and it increases when the head decreases. This adds one more difficulty to the problem of balancing the axial thrust, especially in low-lift pumps.

Correspondingly, the velocity diagram at the periphery is influenced by the secondary components. The higher pressure corresponds to a lower velocity and *vice versa*. The effect is suggested in Fig. 21. Again, the variation of the velocity diagram is enhanced by the following peculiarities of the low-lift runner:

a.—The unfavorable degree of curvature, $\frac{R}{d}$, entails a great difference between the radial component, v_2, of the relative velocity at the inner (v_{2_i}) and outer (v_{2_o}) side of the bend.



VARIATION OF VELOCITY ACROSS WIDTH OF IMPELLER AT PERIPHERY.

FIG. 21.

b.—The absolute discharge velocity, c_2, is influenced more by v_2 when the circumferential velocity u_2, is comparatively small, that is, when the ratio, $\frac{v_2}{u_2}$, is high.

c.—The angle, δ_2, between absolute (c_2) and peripheral (u_2) velocity, again varies considerably more if $\frac{v_2}{u_2}$ is high.

The fluid leaves the impeller under a steeper angle, δ_2, at the left side than at the right. As the guide- or diffusor-blades are without exception made cylindrical, that is, curved in only one plane, it is impossible, on principle, that at any duty all threads of fluid should

at all points enter the guide-channels parallel to the guide-blades, that is, "without shock", as the term is used.

The loss due to this cause will reach a minimum when the angle of the guide-blades is somewhere between the two extremes of δ_2, as suggested in Fig. 21. As velocities at this point are very considerable, the efficiency, especially of large medium-lift pumps, can be appreciably improved if the angle of the guide-blades is not based on the usual diagram of discharge velocities, but on such a diagram as Fig. 21, choosing a value for α_3 somewhere between the two extremes. Experiments conducted by Messrs. Sulzer Brothers, in Winterthur, Switzerland, with a view to determining the influence on the efficiency of such variation of δ_2, have shown that this point well deserves the attention of designers.

As the lack of parallelism of the water threads is generally much more noticeable in low-lift pumps, a further reason is added to the considerations which make guide-wheels less desirable in low-lift than in high-lift pumps.

The advisability and good effect of leaving ample play between the points of impeller and diffusor blades need only be hinted at, in relation to this matter.

The importance of the ratio, $\frac{D_2}{D_1'}$, becomes apparent. A high value of this ratio removes the chance of seeing the pump perform surprising feats when tested; it is easier to guess beforehand the exact pressure generated by the pump; instability and noise, etc., are less likely to occur unexpectedly. On the other hand, difficulties are bound to arise if a runner with a small ratio of diameters, for instance, $\frac{D_2}{D_1'} \leqq 1.5$, has to suck the water through a sharp bend as shown on Fig. 19. The depression forming at the point, A, Fig. 19, serves to enhance the depression at A', Fig. 20. The induced current becomes so strong that a complete vortex may be formed at times, resulting in a surprising reduction in capacity, instability of action, noise, lack of efficiency, etc.

The designer's influence on the determination of that decisive ratio, $\frac{D_2}{D_1'}$, is rather limited. The entrance diameter, D_1, is either fixed by standardized manufacture or, at all events, dependent on the capacity. D_2 is given by the required head and speed of the pump. Espe-

cially the problem, so prominent at present, of coupling water-works. irrigation, or drainage pumps direct with high-speed motors or steam turbines nearly always places the designer in a quandary. The head is low and the speed high; therefore D_2 is very small. The capacity is great; therefore D_1' is large. The expedient of reducing D_1', by splitting the capacity and coupling two or more impellers in parallel, generally is barred by competitive reasons, for this means a considerable increase in weight, selling price, and floor space required by the pump.

The outcome of such a proposition is shown by the upper half of Fig. 22, which is taken from a publication of a well-known American manufacturing concern. In order to prevent instability of flow, an elaborate system of radial entrance guide-vanes, A, was introduced. From the writer's experience it would seem to be doubtful whether much could be accomplished thereby. Judging from the knowledge of induced currents, it is clear why the effect of radial guide-vanes should in general be comparatively insignificant.

In spite of the efforts of the designer to "guide" the water, the compartments between the fixed radial blades remain bends of a very unfavorable degree of curvature. The entrance velocity of the fluid must be chosen high by the designer in order to diminish D_1' as much as possible. Instead of at the even pressure, H_1, as indicated on the right-hand pressure diagram, the water in reality must enter the compartments at pressures which vary about as shown in the left half of the diagram.

Worse still is the corresponding variation in speed, which results in heavy losses through discrepancy of angles at the entrance of the impeller. Until the water reaches the circumference of the impeller, this difference must be further emphasized. The resulting mean pressure, H_{2_m}, may even drop below the expected amount, H_2. In any event, the water will leave the impeller in a greatly disturbed condition, which will not add to the efficiency of the pump.

The depression at the point, P, may even lead to a separation of air or vapors. From the knowledge of induced currents, a suggestion might be made which would seem better to serve the purpose and which is sketched in the lower half of Fig. 22. This arrangement does not require more space than the former. By introducing an intermediate profile, C, the degree of curvature is improved very consider-

ably, for both of the newly formed halves of the runner. In order fully to utilize this advantage, the inlet chamber, too, should be divided in two by a cylindrical guide, A'. Though, no doubt, the impeller will become a more complicated casting and, therefore, more expensive

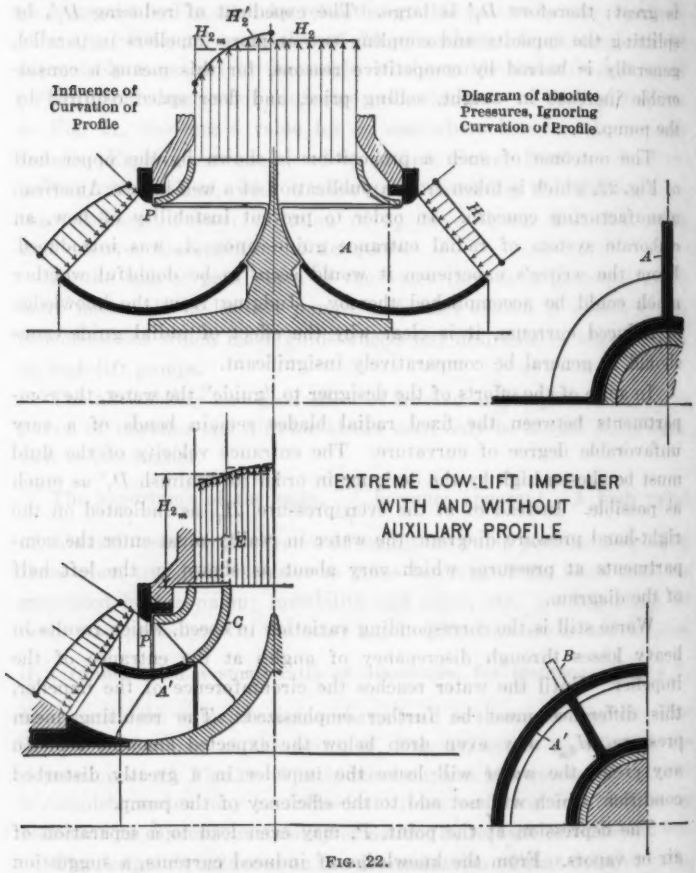


FIG. 22.

in manufacture, the new guide is considerably smaller and cheaper than the radial guide-blades, A, shown in the upper half of Fig. 22. Exterior radial ribs (as shown by the dotted lines at B on the lower right cross-section) may or may not be resorted to, in addition to the

cylindrical guide, A'. By doing away with them in the outer half of the inlet throat (as shown in the lower left section), the advantage is secured of having the water rotate somewhat around the axis of the pump, owing to the friction of the impeller. This counteracts the depression which forms at the point, P. Incidentally, in the arrangement shown in the lower half of Fig. 22, the passage area of the throat is made steadily to decrease, thus securing the steadying effect of a nozzle for straightening out irregularities of flow at the entrance of the impeller.

The result of this and of halving the width of the cells is suggested in the pressure diagram erected over the width of the impeller outlet. The extreme pressure differences should be reduced in both halves, as compared with the arrangement shown in the upper half of Fig. 22. The danger of a break in continuity is substantially removed.

A new difficulty arises: both the absolute and the mean pressures are different on both sides of the auxiliary profile. In addition, the direction and speed of flow will differ at this place. Dr. Lell's experiments tend to show that the eddies which must result therefrom do not nearly absorb the increase in final pressure which actually does occur by inserting an auxiliary profile. Besides, it will often be possible, without great difficulty or complication, to provide for a short auxiliary wall, E, which keeps the two streams apart until their velocity has decreased sufficiently.

An obvious objection to the suggested alternative will be directed against the increase in loss of head which should result from the additional area of friction introduced by the intermediate partition, or, in other words, from the diminution of the hydraulic radius. No doubt the auxiliary profile does increase that part of the loss of head which is directly due to wall friction. The losses due to the induced currents, however, which are a multiple of the friction losses, are reduced. Their reduction is of much more importance than the increase in wall friction.

That this contention is correct was proved by Dr. Lell. He inserted in Pfarr's experimental bend an auxiliary partition forming a concentric cylinder, of 170 mm. radius, and of the same smoothness or roughness as the walls of the bend. Though, by this insertion, the total area of the walls was increased by 26%, the loss of head in the bend proper decreased by 20 to 25 per cent. In Fig. 12 the curve

of dashes and dots, marked, "With partition (equalized)", furnishes a means of comparing the losses occurring with and without such partition.

Lell's investigations also proved the advantageous effect of continuing the partition some little distance into the straight duct following the bend. For these and similar details the writer must necessarily refer those interested to Lell's paper.

It should be emphasized that the advantage to be derived from an auxiliary partition in the impeller is not only the decrease in loss of head through the curvature of the impeller profile. This, in itself, would not amount to very much. If 5% of the total energy transformed in a turbine pump were lost in the impeller proper, a reduction of such losses by 20% would only improve the efficiency by 1 per cent.

The deviation of actual velocity diagrams at the entrance and discharge of the impeller from the theoretical diagram is much lessened by the introduction of the auxiliary partition. This fact should influence the efficiency, directly and indirectly, much more favorably than the mere reduction of impeller resistance.

3.—Diffusor Vanes.—It is difficult to derive more than a few general points of view regarding guide-wheels of turbine pumps from the experimental data which are available at present. Gibson, in a noteworthy paper,* has put down a few suggestions as to how, on the basis of his experimental evidence, the channels of guide-wheels could most advantageously be shaped. The writer would refer those interested to that paper.

The fact that, in most instances, the axis of the guide-channel must, from constructive reasons, be curved concavely toward the impeller, gives a special importance to the curvature of the outer wall (o — o in Fig. 23) of the channel. Some designers are of the opinion that, in multi-stage pumps, the fluid should be "gradually guided into a radial direction before being led back from the periphery of the casing to the inlet of the next stage". The object is to avoid the formation of a vortex in the chamber, C. They, therefore, favor a change in the sense of curvature of the wall in question, about as shown by the dashed curve in Fig. 23. This is not good practice. The water refuses to be "guided". Instead, the abrupt opening out of the cross-section connected with the change of curvature often generates strong

* *Engineering*, February 16th, 1912, p. 205.

and obnoxious induced currents which seriously impair the efficiency, at least in all instances where the velocity of the fluid is still high at the turning-point of the vane. On the other hand, there is no danger in tangential forces which are exercised by the streams leaving the guide-channels, as long as radial ribs, *D*, are provided for in the chamber, *C*. These are not to be dispensed with in any event, even if the guide-channels "pour out radially"; for there is always the twist due to the induced currents developed in the curved guide-channels.

This "twist" or corkscrew motion is also present in the streams of water which leave the impeller. Andres' investigations on the effect

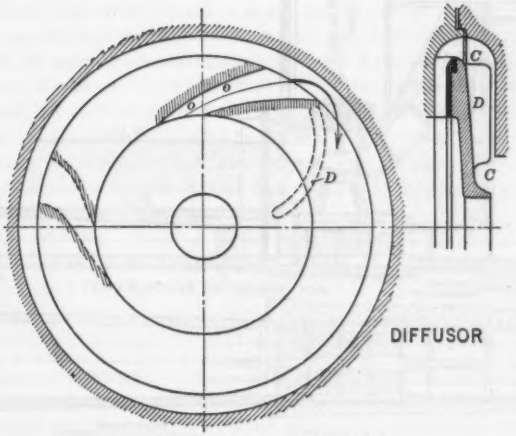

FIG. 23.

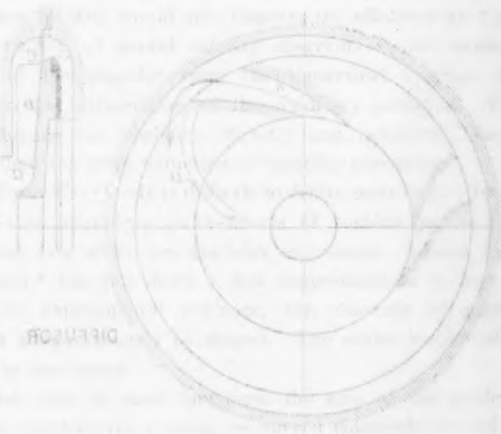
of rotation of the fluid around the axis of diffusors indicate that it is due to this spiral motion that the efficiency of diffusor channels in pumps seems to be tolerably high, in spite of the odd shape which the designer generally has to give them.

By the foregoing suggestions the writer feels that he is just skimming the possibilities of improvement based on a fuller knowledge of the induced currents of fluids. A fair proportion of this knowledge is at hand. Designers of hydraulic and pneumatic machinery should at least be able to derive some valuable aids from it to induce them to slacken their hold on the theory

of stream lines and to develop a wider and more correct conception of the actual flow of fluids. This cannot but lead to very substantial improvements in many directions.

Meanwhile, it will be incumbent on technical physics to supply more specific information about all details connected with the generation of induced currents of fluids.



DISCUSSION

Mr. Herschel.

CLEMENS HERSCHEL,* M. AM. SOC. C. E. (by letter).—A special case of induced currents of fluids is shown by the currents flowing into the throat of a Venturi tube from the outside, when thus allowed to flow in by suitable orifices. The writer has experimented on such currents on an unusually large scale, these experiments being described in a paper entitled "The Fall-Increaser", in the *Harvard Engineering Journal* of June, 1908. This is an account of experiments made to establish the

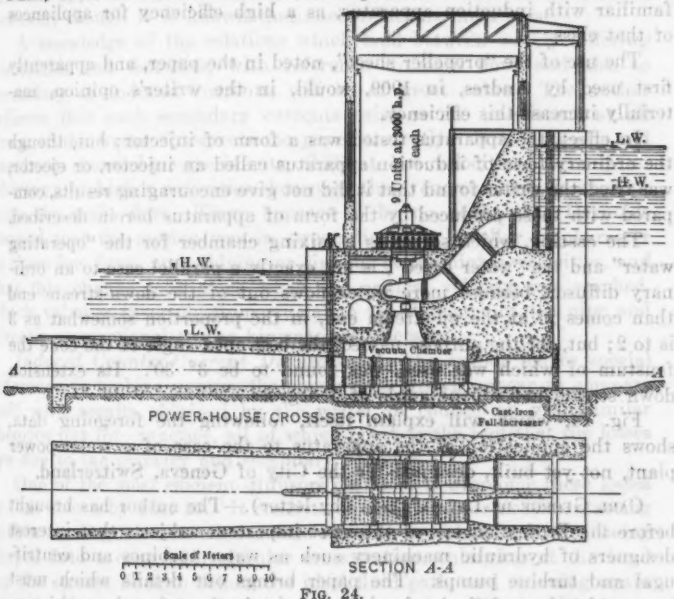


FIG. 24.

proper proportions of an apparatus called the "fall-increaser", designed to utilize, for power purposes, freshet water otherwise going to waste over the dam, in the case of water-power plants, on rivers having a suitable régime, when situated adjacent to, or not far distant from, the dam.

As the *Harvard Engineering Journal* is rarely seen, the results of the experiments alluded to may properly be recorded in conjunction with those referred to in the paper.

The experiments were conducted accurately at the Holyoke, Mass., public testing flume, all the water experimented with being measured

* New York City.

Mr. Herschel. continuously with two Venturi water meters. The "operating water" was in some of the tests as much as 14 sec-ft.; the "water lifted" (entering the tube by induced current), 7 sec-ft.; the natural, or "operating head", up to 14.35 ft.; the "head gained by the use of the fall-increaser", up to 12.52 ft.; and the penstock, 16 in. in diameter. With this apparatus, a vacuum, measured by more than 26 ft. of water column, could be produced and steadily held suspended; its efficiency, reckoning for water lifted a certain height, by water falling a certain height, as a maximum found, was 30.4%, which will be recognized, by those familiar with induction apparatus, as a high efficiency for appliances of that class.

The use of the "propeller sheet", noted in the paper, and apparently first used by Andres, in 1909, would, in the writer's opinion, materially increase this efficiency.

In effect, the apparatus tested was a form of injector; but, though the ordinary form of induction apparatus called an injector, or ejector, was tried, the writer found that it did not give encouraging results, compared with those produced by the form of apparatus herein described.

The casting, which serves as a mixing chamber for the "operating water" and the "water lifted", is not exactly a parallel case to an ordinary diffusor, because more water flows out of the down-stream end than comes in at the up-stream end, in the proportion somewhat as 3 is to 2; but, for the purpose named, the best apex angle of the cone the frustum of which was used, was found to be 3° 30′. Its extension down stream had a cone angle of 5 degrees.

Fig. 24, which will explain itself, following the foregoing data, shows the application of the apparatus to the case of a water-power plant, not yet built, designed for the City of Geneva, Switzerland.

Mr. de Laval. CARL GEORGE DE LAVAL,* ESQ. (by letter).—The author has brought before the Profession one of the most important subjects that interest designers of hydraulic machinery such as water turbines and centrifugal and turbine pumps. The paper brings out details which must be considered carefully in the design and selection of such machinery, and have only been known to a few within comparatively recent years. It is safe to say that a great many hydraulic machines have been designed by the purest guesswork, but, owing to the call for increased efficiencies and economy in operation in all the applications to various plants, the problems have received careful and intelligent study, causing many improvements, with more to come, when such papers as this bring them before the Profession for further thought.

It is admitted that improvements are hampered by the scarcity of published data from experiments, and, therefore, such a collection of

* Gen. Mgr., Worthington Pump Co., Ltd., Harrison, N. J.

data as the author presents will give valuable information for the use of manufacturers. Mr. de Laval.

In the evolution of centrifugal and turbine pumps no factor has played a greater part in obtaining increased efficiency than the study of the laws of the surface friction of fluids. This subject has been under investigation by the most eminent engineers for more than 100 years, and to-day the laws governing the velocity of flow for a particular fluid are tolerably well known. Experiments establishing a general relation applicable to all fluids and conditions of flow are not known, however, though it is known that such relations must exist.

A knowledge of the relations which hold between widely differing viscosities and densities, with reference to main flow, and also to secondary or induced currents, will be of great value. The author believes that such secondary currents exist or are co-existent at all flows, if the writer interprets the paper correctly. It is believed, and has been shown by experiments, that, at low velocities, there is no eddying; at higher velocities, however, these currents are co-existent with the main flow. There appears to be no doubt that Reynolds showed that the motion was in stream-lines, or lamellar in character at these low flows, and eddying or sinuous at the higher velocities, and that this change took place when the critical velocity was reached, which value is inversely proportional to the diameter of the pipe and directly proportional to the kinematical viscosity.

Induced Counter-Current Diffusors.—As the author makes special reference to turbine pumps, the conclusions drawn appear to compare well with results obtained by the writer in connection with similar theories put into practice, all of which point to the fact that the losses are due to the primary and secondary currents.

One of the most efficient diffusors designed to overcome these losses is that shown by Fig. 25. It consists of eight diffusor nozzles, starting with a rectangular section near the impeller periphery and then being shaped into a cone with circular cross-section, enlarging at the bend for the stream lines to follow the ideal fluid path, and reducing again to a circular section for the next impeller supply. This bend is circular, and will show a difference of pressure between the outer and inner points, due to the centrifugal force of the water flowing through them. This difference can be ascertained. The result is a vortex set up at the inner surface, which can be eliminated when the water is swept clean, due to secondary currents which also set up a rotary motion while passing through the diffusors.

The discharge from these eight diffusors is exactly the same as that from eight nozzles discharging parallel to the axis of a turbine pump. This arrangement appears to bear out the author's theory, and was applied by the writer on some important installations of turbine pumps with 250 ft. per stage, and gave a remarkable efficiency of

Mr. de Laval.

86 per cent. There was every indication, after the experiments were made with diffusors of this shape, that they gave a diffusion efficiency as high as 99.5%, and fully substantiated the proofs of Andres' experiments.

Transverse Induced Currents.—In considering this subject the writer believes that there are two critical velocities which must be taken into account: one is the velocity due to the fluid entering with a high state of turbulence, passing from an eddying to a stream-line motion; the other is that in which an undisturbed fluid enters with a

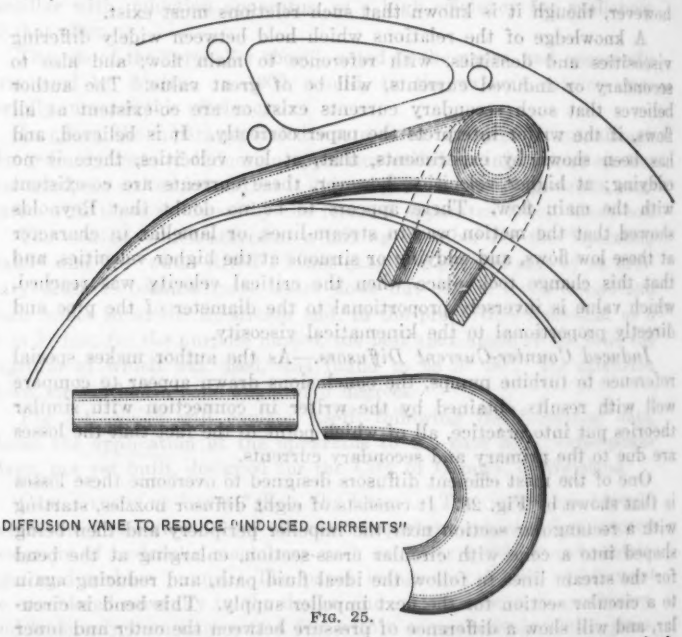

FIG. 25.

stream-line motion which exists until the critical velocity is reached before breaking into an eddying motion. This is just what takes place in elbows, bends, and suction or entrance heads to centrifugal pumps. The theory, after mathematical survey by the author, appears to give a good insight into the subject, with, perhaps, such modifications of the position of the elbow as relate to a consideration of the rotation of the impeller which is to receive this water finally.

Fig. 26 shows a design of the suction entrance of a pump having one turn or elbow for the water. This embodies the theory of gradually increasing the velocity in order to produce a vortex at the impeller

hub. It is to be noted that the upper section is divided like a heart, and stream lines are directed toward a cone at the impeller entrance. Mr. de Laval.

Fig. 27 shows a design of an entrance intended to obviate these induced currents, where the water has to enter horizontally at right angles to the rotation, and is properly fed or directed to the runner. Owing to the fact that the water receives a rotary motion, and that

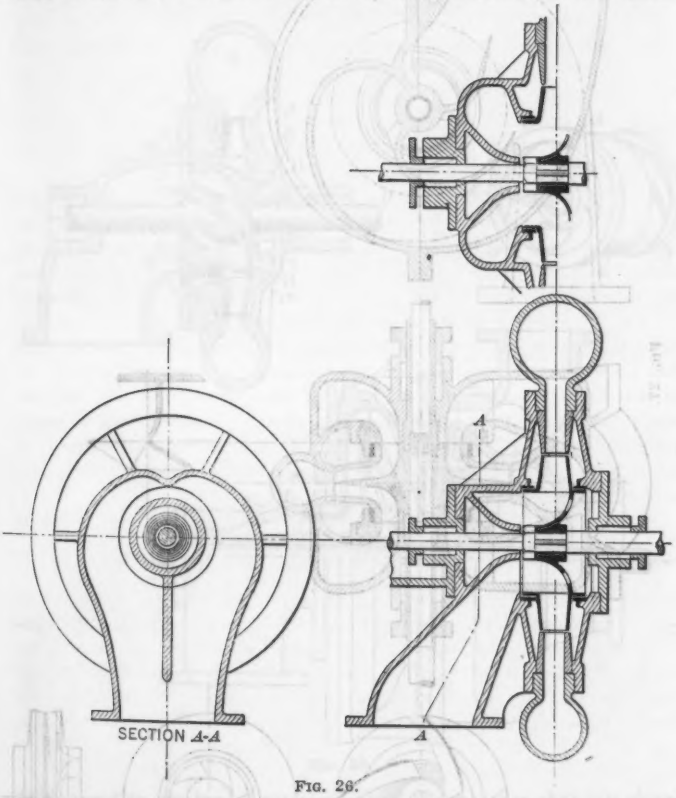

FIG. 28.

in this case there are a great many induced currents, the inflow of water to the runner would be greatly impaired and probably reduced considerably. This was shown by experiments similar to von Cordier's tests indicating by pressures at various points the various areas and places where these induced currents took place; they also revealed the fact that it was necessary to prevent the whirling of the particles in an

Mr. de Laval.

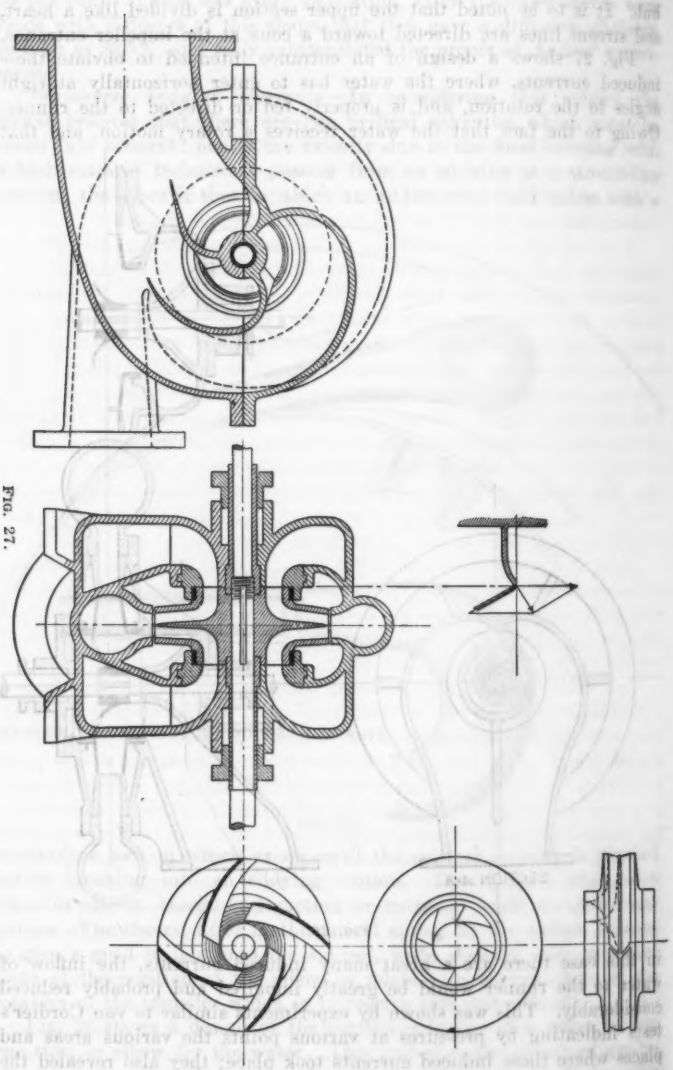

FIG. 27.

irregular manner and direct them into a well-defined path forming two or more streams or currents. Mr. de Laval.

The results showed that this theory was correct, and that, by making the suction chamber heart-shaped, shutting off the supply to the runners nearest the entrance, and dividing the stream into two or more nozzles, producing a volute chamber, the rotary motion of the

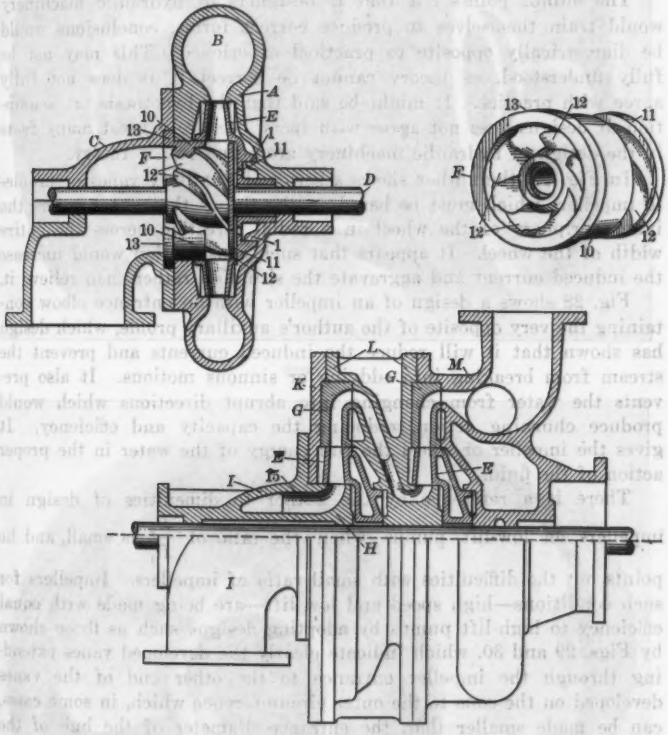

FIG. 28.

water, based on the law of rotation, swept the entrance channels clean, thus preventing a critical velocity which would have started or broken into eddying motion. The final results showed cases where the capacity was increased from 40 to 50% on otherwise the same construction.

In the conversion of kinetic into pressure energy, such as is to be considered in the design of hydraulic piping and machines, the passages have to be increased or decreased suddenly to reduce the

Mr. de Laval.

velocity of flow, and in converting a part of this into pressure energy many difficult problems are met, the laws of which are but little known. If, however, experiments are undertaken to establish these points, data are obtained which are suitable for all practical purposes, and these few results, given in a general way, may aid others to derive some information.

The author points out that if designers of hydraulic machinery would train themselves to produce correct forms, conclusions would be diametrically opposite to practical experience. This may not be fully understood, as theory cannot be correct if it does not fully agree with practice. It might be said that the hypothesis or assumption of designs does not agree with facts, because a great many facts in the design of hydraulic machinery are borne out by theory.

In Fig. 22, the author shows a series of auxiliary vanes or profiles to impellers which must be based on the theory that water enters the inner periphery of the wheel in a radial direction across the entire width of the wheel. It appears that such construction would increase the induced current and aggravate the situation rather than relieve it.

Fig. 28 shows a design of an impeller with an entrance elbow containing the very opposite of the author's auxiliary profile, which design has shown that it will reduce the induced currents and prevent the stream from breaking into eddying or sinuous motions. It also prevents the water from changing into abrupt directions which would produce churning action, reducing the capacity and efficiency. It gives the impeller or wheel the full energy of the water in the proper action of the fluid.

There is a reference by the author to difficulties of design in impellers on low-lift pumps when the ratio of $\frac{D_2}{D_1}$ is small, and he points out the difficulties with small ratio of impellers. Impellers for such conditions—high speed and low lift—are being made with equal efficiency to high-lift pumps by adopting designs such as those shown by Figs. 29 and 30, which indicate clearly the developed vanes extending through the impeller entrance to the other end of the vanes developed on the cone to the outer circumference which, in some cases, can be made smaller than the entrance diameter of the hub of the impeller. Such impellers give a remarkably high efficiency for low heads and high speed. The method of layout for such vanes is shown by Fig. 31.

Another method for inducing the flow to the impellers by guide nozzles is shown in Fig. 32. These references are given to show that there are other ways of obviating the defects referred to by the author, without resorting to expensive auxiliary partitions in the impellers.

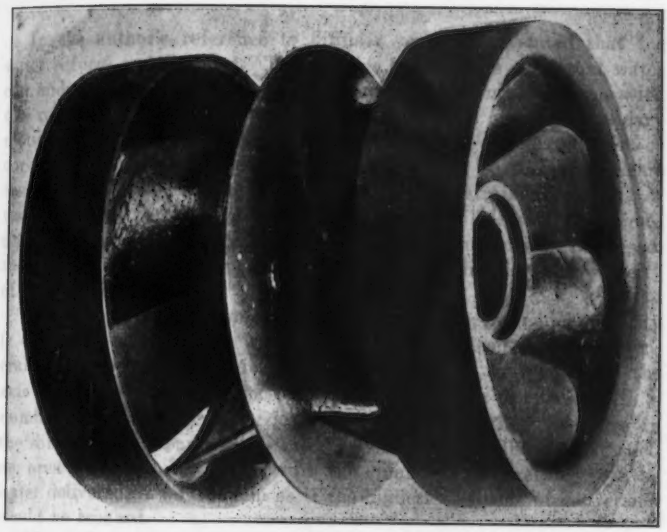

FIG. 29.

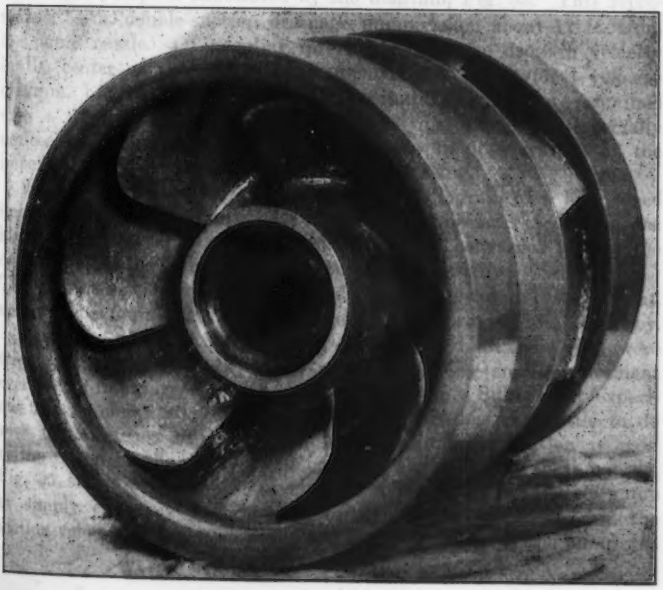

FIG. 30.

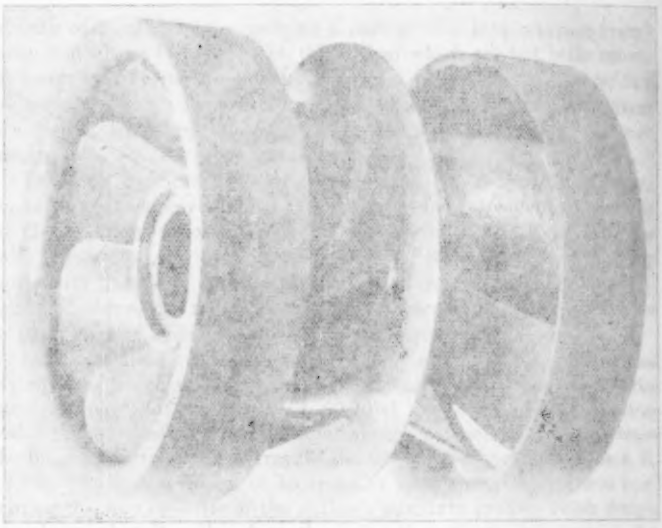

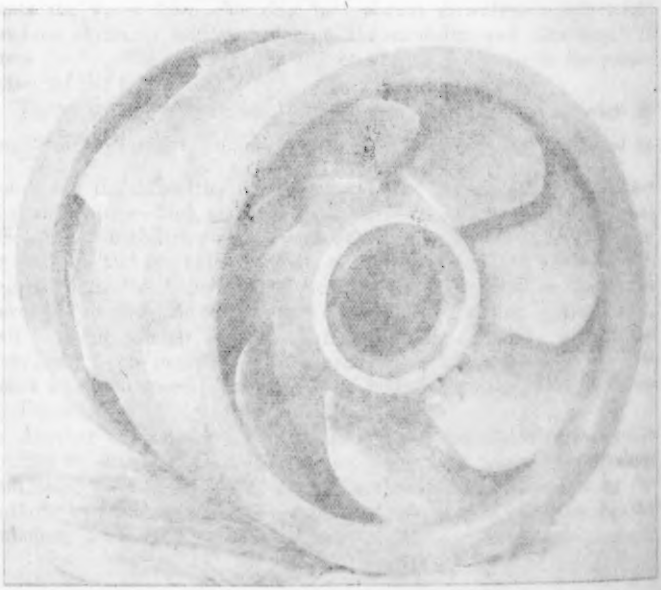

Mr. de Laval.

In the author's reference to diffusor vanes, it is stated that the water refuses to be guided. The writer's experiments show that water can and must be guided, but, at the same time, it must be done with due regard to the main motion of the stream lines and the secondary motion of the induced currents, introducing the necessary twist or corkscrew action with a nozzle discharge, which, so to speak, clears the passages. The writer believes that the unrestrained particles of water from the periphery of a rotating impeller will leave in a tangential direction at a tangential velocity. As the quantity is increased, the direction and velocity are modified by the direction and velocity of the radial flow.

The proportions of conical nozzles are known, in which velocity is converted into pressure with the least loss of head, and it is generally accepted that a conical pipe with a proper indirection to the axis is the best. As it is possible to surround the periphery with a number of such conical nozzles arranged so that their axes are in the direction of a particle of water leaving the impeller and of such an area at the throat as to suit the quantity and velocity of the water delivered, it would seem as if the highest efficiency of conversion would be reached.

The influence of runner curvature on the discharge velocity in centrifugal pumps is illustrated by the diagram, Fig. 33. This represents a 54-in. double-suction drainage pump, taken about 12 ft. from the pump nozzle. Of peculiar interest will be the drop in velocity in the center of the pipe when compared with the typical velocity diagram, Fig. 2, and with Fig. 22. Similar results were obtained with a number of different pumps. The disturbance is especially noticeable in high-speed pumps, due to the small curvature of the impeller as well as the small radius of the casing.

In Fig. 22, the author shows the velocity diagram of a high-speed impeller with radial components of respective pressures. Experience has shown, however, that the direction of flow converges toward the center, even if the ends of the curvature point radially. (See Fig. 34.) This fact must be kept in mind when designing the volute casing throat, and will be found of extreme influence in improving the efficiency.

Impellers with auxiliary profile, as suggested on page 892, were tried by the writer in 1910, but without showing any improvement over the ordinary type, and have been given up. Subsequent experiments have shown that the degree of curvature has very little to do with the efficiency of the pump, provided proper attention is paid to the shape of the inlet. The common suction elbow will not do. Fig. 35 shows a series of experiments made on a high-speed pump by simply changing the contours of the suction approach and the suction velocity. If it is considered that the efficiency of the pump was

Mr. de Laval.

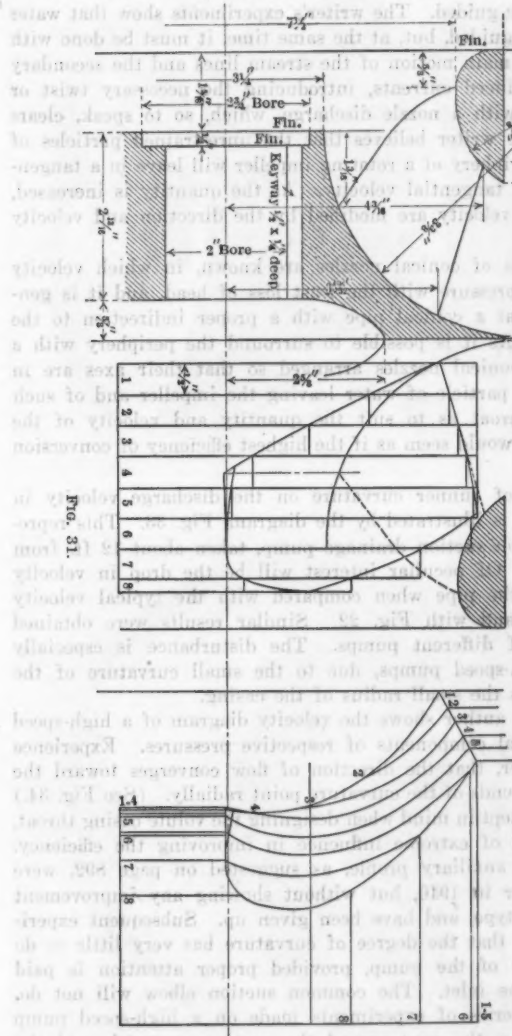

Fig. 31.

raised from 40 to 71%, without any change in the impeller or in the casing, the importance of this will be readily seen. The influence of a properly directed inlet is not so apparent on slow-speed pumps. This Mr. de Laval.

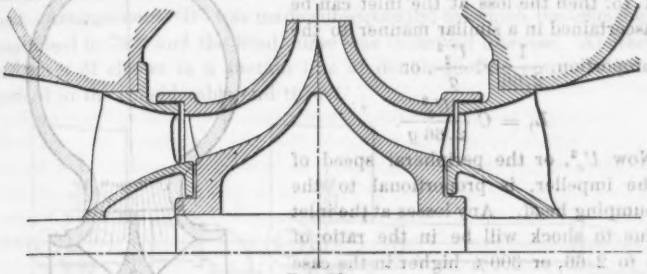

FIG. 32.

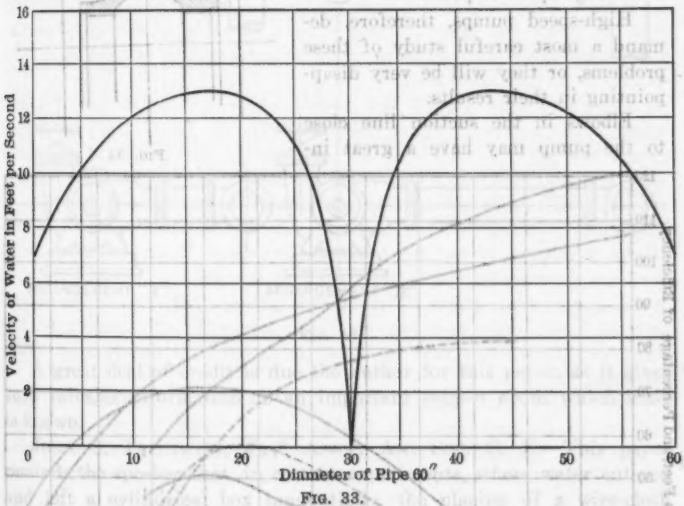

FIG. 33.

can be explained by the speed at which the water is picked up by the vanes. Take, for instance, an impeller with a ratio of

$$\frac{\text{outside diameter}}{\text{suction inlet diameter}} = 2,$$

then the velocity of the inlet, U_s, is equal to one-half the velocity at the outer diameter, U_2. Any shock losses at the inlet will be proportional to

$$\frac{U_s^2}{2g}, \text{ or } \frac{1}{8}\frac{U_2^2}{g} L = C\frac{U_2^2}{8g}.$$

Mr. de Laval.

Let us take now an extreme high-speed impeller with a ratio of $\frac{D\,a}{D\,s} = 1.15$: then the loss at the inlet can be ascertained in a similar manner to the proportion, $\frac{1}{2.66} \times \frac{U_2^2}{g}$, or

$$L_1 = C\,\frac{U_2^2}{2.66\,g}.$$

Now U_2^2, or the peripheral speed of the impeller, is proportional to the pumping head. Any losses at the inlet due to shock will be in the ratio of 8 to 2.66, or 300% higher in the case of the high-speed impeller.

High-speed pumps, therefore, demand a most careful study of these problems, or they will be very disappointing in their results.

Elbows in the suction line close to the pump may have a great in-

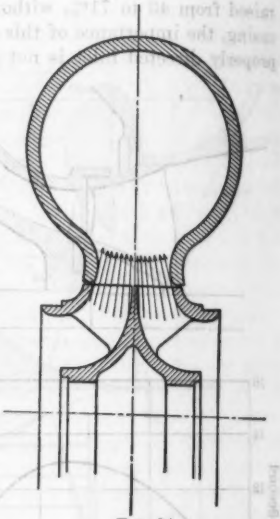

FIG. 34.

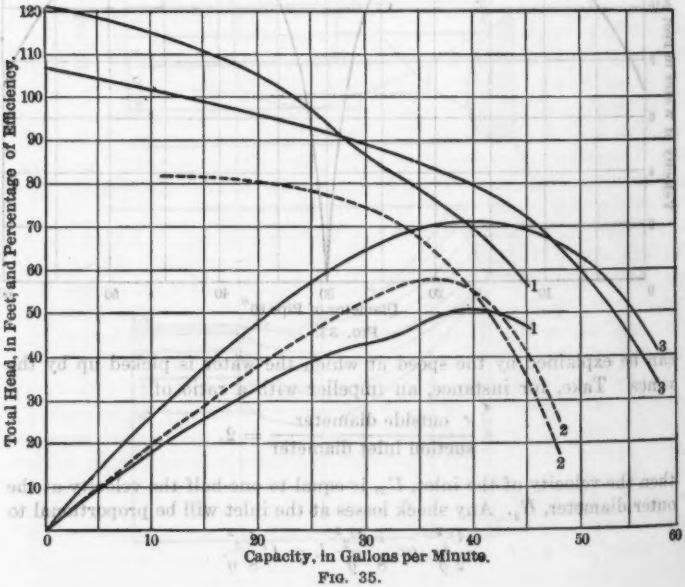

FIG. 35.

fluence on the characteristics of the latter. Fig. 36 shows a 14-in. pump. Arrangement "A" was made with a standard long-sweep elbow, 3 ft. from the pump nozzle, with a pump efficiency of 65 per cent. Arrangement "B" was made subsequently, by which the efficiency was raised to 75% and the head curve was improved likewise. Another bad effect of elbows in a suction line of double-suction pumps will be noticed in the considerable end thrust. Mr. de Laval.

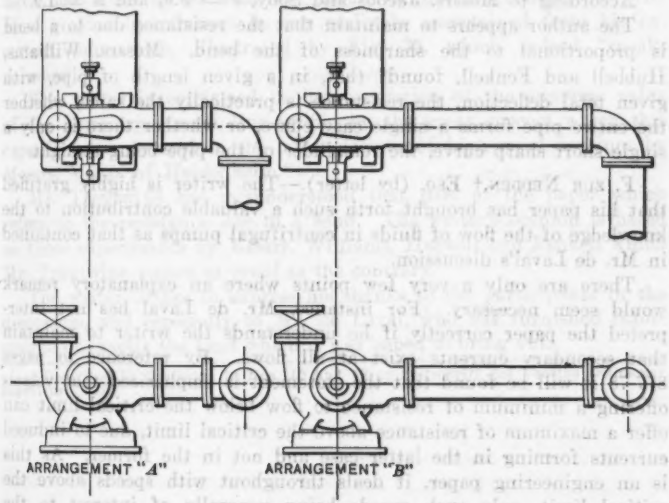

FIG. 36.

A great deal of credit is due the author for this paper, as it gives such valuable information on an important subject about which little is known.

JOHN C. TRAUTWINE, JR.,* ASSOC. AM. SOC. C. E.—This paper reminds the speaker that, in certain experiments, where water entered and left a cylindrical box tangentially, the placing of a wire-cloth screen in the box, instead of increasing the loss of head, as expected, diminished that loss, evidently by diminishing or destroying the centrifugal force, due to the previously unchecked rotary motion of the water. Mr. Trautwine.

The speaker is reminded also that Messrs. Gaskell S. Jacobs and F. A. Sooy have described† a simple method, devised by Mr. Buckner Speed, of measuring the velocity of water flowing through a pipe in which a bend occurs. This consists simply in tapping the bend on

* Philadelphia, Pa.

† *Journal of Electricity, Power and Gas*, San Francisco, July 22d, 1911.

Mr. Trautwine.

its outer and inner sides. Then, if h equals the difference in pressure, in feet, between the outside and the inside of the bend, R equals the radius, in feet, of the bend described by the pipe axis, and d equals the pipe bore, in feet; we have, for the velocity, in feet per second,

$$v = c\sqrt[n]{h\frac{R}{d}}.$$

According to Messrs. Jacobs and Sooy, $c = 5.6$, and $n = 1.9$.

The author appears to maintain that the resistance due to a bend is proportional to the sharpness of the bend. Messrs. Williams, Hubbell and Fenkell, found* that, in a given length of pipe, with given total deflection, the resistance is practically the same, whether the entire pipe forms a single easy curve, or whether there is only a single short sharp curve, the remainder of the pipe being straight.

Mr. zur Nedden.

F. ZUR NEDDEN,† ESQ. (by letter).—The writer is highly gratified that his paper has brought forth such a valuable contribution to the knowledge of the flow of fluids in centrifugal pumps as that contained in Mr. de Laval's discussion.

There are only a very few points where an explanatory remark would seem necessary. For instance, Mr. de Laval has not interpreted the paper correctly if he understands the writer to maintain that secondary currents exist at all flows. By reference to pages 877-78 it will be found that the statement is emphasized that vessels offering a minimum of resistance to flow below the critical limit can offer a maximum of resistance above the critical limit, due to induced currents forming in the latter case and not in the former. As this is an engineering paper, it deals throughout with speeds above the critical limit, only such speeds being generally of interest to the engineer; those below that limit fall mostly within the domain of the physicist.

The two critical speeds which Mr. de Laval mentions on page 900 are of no importance to the engineer. From the use he makes of the term "critical velocity" later (on page 903), it would seem that he means by it something quite different from the well-defined scientific term.

It certainly is a source of great satisfaction that the results obtained from diffusors such as Fig. 25 confirm the writer's theories in such a remarkable way.

Fig. 26 is an example of the practical application of the writer's recommendation to steady the flow at the entrance to impellers by decreasing the area. The same is true of the auxiliary inlet vanes such as Fig. 32.

* *Transactions*, Am. Soc. C. E., Vol. XLVII, April, 1902.

† New York City.

Mr. zur Nedden.

It is gratifying to have as complete a vindication of the writer's thesis as the following sentence on page 907 by Mr. de Laval, one of the highest authorities among pump manufacturers in the United States: "The common suction elbow will not do."

The alleged bad experiences of Mr. de Laval with his auxiliary profiles is not considered as conclusive evidence against the expedient recommended by the writer. The shape of the entrance chambers might have had much to do with the failure of his experiments in 1910. How great this influence is, can easily be ascertained from his excellent comparison, illustrated by Fig. 35, which indeed "speaks volumes".

The writer is confirmed in his conviction of the supreme value of the auxiliary stream line profile by the great success which this expedient has secured in the latest designs of high-speed turbines by Messrs. Voith, of Heidenheim.*

Mr. Trautwine has misunderstood that part of the paper which refers to the resistance due to a bend. The writer's opinion is based on those experiments by Messrs. Williams, Hubbell and Fenkell which Mr. Trautwine quotes as proof to the contrary.

The writer wishes to express his thanks to the participants in the discussion, and especially to Mr. de Laval, who has furnished information of exactly the kind which it was hoped to bring out.

Paper No. 1365

SECURE SUBWAY SUPPORTS*

By A. B. Lueder, M. Am. Soc. C. E., and W. J. R. Wilson, Esq.

With Discussion by Messrs. H. G. Moulton, Richard A. Fiesel, J. H. O'Brien, B. C. Collier, Lazarus White, and A. B. Lueder and W. J. R. Wilson.

Synopsis

The object of this paper is to describe the problems met in the construction of Section 13 of the Lexington Avenue Subway, New York City, to state how those problems were solved, and to give the reasons for the methods selected.

Deep and wide rock cuts made Section 13 one of the most difficult parts of the subway work. It was necessary to have an improved system of street supports in order to insure safety, and attempts were made to forsee such dangers as those caused by blasting and by rock slides. The advantages to the contractor in using massive supports and continuous steel beams are argued, and descriptions of the towers and beams are given, as well as the methods of putting them in place.

The main conclusion of the paper is that the safety of city streets during subway construction will be better guaranteed if a comprehensive design of street supports, made by competent engineers, is bid on as part of each contract.

This paper describes a street supporting system, designed by the writers and used in the construction of Section 13 of the Lexington

* Presented at the meeting of February 16th, 1916.

Avenue Subway, New York City, for the contractors, McMullen-Snare and Triest, during the period, 1912 to 1914. Section 13, which extends from 118th to 129th Street, was one of the most difficult on the New York subways, owing to the varying depths—from 30 to 60 ft.—and the varying widths—from curb to curb in the shallow parts to practically the full width of street from building to building in the deep section. The corkscrew arrangement of the tracks in this section made the design of the bottom most irregular, often requiring four different levels, with a variation as great as 20 ft. in the rock bottom across the cut. The permanent structure was so irregular that practically every one of the six hundred steel bents was different. The material excavated varied from quicksand to the hardest kind of rock. The rock surface was also very irregular, being sometimes at the street surface and sometimes not found 60 ft. below. The rock itself was typical Manhattan schist and Inwood limestone, probably harder on the whole than that found in the lower part of the city, and containing many mica seams and other faults so common in New York rock. Very sharp dips transversely across the cut were frequently encountered.

In the design of the street supporting system, it was felt that the most important feature was the likelihood of New York rock to slide suddenly—a very serious danger in a deep cut. It was decided, therefore, that the supports should not rest on the rock at the sides, but on the rock bottom in the center of the cut, where they would be farthest from danger if a slide occurred, and would be directly under the street-car tracks, the heaviest load to be carried.

Any system of street support, to be effective from the standpoint of the contractor's engineers, must guarantee absolute safety to the public, must give ample working room, and must be economical as regards cost of construction and erection. In the special case, adaptability to the conditions required a most flexible scheme. A contractor cannot afford to pay damages to the public, nor does he wish that kind of advertising. The public is entitled to a design with a large factor of safety, because its members must of necessity use the streets, and are helpless to safeguard themselves against unseen dangers beneath the street surface. The contractor may feel that he can risk his money or his plant sometimes on work, but the contractor's engineer should not involve the public in any risk on designs that he makes. A subway under construction always causes

a certain amount of inconvenience to the public, especially to the business men along the route, and has never been entirely free from a certain number of minor accidents, due to concussion from blasting or irregularities in the temporary street surface. The life of wooden decking is short. The public will be glad to have the job completed in the shortest possible time.

The contractor's profits will vary to a large extent with the time he takes to do the work. Every contractor realizes that there are twice as many Sundays, nights, holidays, and bad-weather days in two years as there are in one, and these days mean expenditure without estimate. The money he pays out for watchmen and rentals, and a large part of his overhead expense, will vary according to the time required to do the work. Contracting is a peculiar business in that the profits are distinctly limited by competition, but there is no limit to the losses. The public and the contractor are agreed that subway work should be done with all speed. This is only possible with the use of the most modern plant, requiring that under the street, as above, the contractor must use hoisting engines, heavy skips and cars, and eliminate all the hand labor possible. This necessitates plenty of working room, clear of street supports. Moreover, the fewer the obstructions, the better will be the light, the greater the safety to the workmen and the greater the security because of ease of inspection and adjustment of the street supports. Instead of filling the cut with posts, each supporting an unknown load, with many wedges always uncertainly tight, there should be provided systematically-placed large supports, carrying known loads, by their size and construction better suited to take blasting shocks or to resist slides, and constantly in plain sight. Any impending danger or weakness will then immediately show itself, and, being accessible, can be easily remedied with the use of heavy machinery. In the construction of the permanent structure, for the placing of steel and concrete, the advantages of working room free from obstructions means fewer accidents, more profits, and better permanent work.

The designer, having in mind a system amply strong to carry the street loads, with supports as far removed as possible from the effects of slides, must consider how it will meet the danger due to blasting. The exact effect of a blast cannot be foretold by any one, because of the constantly changing nature of the rock which is

FIG. 1.—TYPICAL ROCK SLIDE, IN LEXINGTON AVENUE.

FIG. 2.—TYPICAL ROCK SLIDE, IN LEXINGTON AVENUE.

being blasted, but experience should teach the designer to make the parts of his system exposed to blasts amply strong to withstand the maximum effect of shocks from flying rock—with intelligent blasting. Rather than strengthen the system still further to withstand careless or excessively heavy blasting, the contractor should have the blasting done by intelligent, experienced men. In a subway cut, this means taking into consideration three points: First, as always, safety, then maximum output, and then minimum of cost for labor and powder used. The blaster should be able to place and load the holes so that the rock will be thrown clear of supports against the sides of the cut, or into a clear space. The intelligent blaster will study the rock constantly, will understand where to drill the holes, and will be thoroughly conversant with the use of dynamite. It is desirable to blast as seldom as possible; that means getting a maximum quantity of muck with each blast. The nearer the blasting and excavation approach the open-quarry method, the greater will be the output, the less the powder used, and the less the number of small flying stones —all this tending to greater safety and lower cost.

The blaster, however, will be helpless if he has not a clear space, free from supports, into which he can throw large quantities of rock in safety. Such blasting brings out the rock in large pieces, and to prevent numerous interruptions to everybody from small pot-hole blasts to break them up, means must be provided for taking heavy masses of stone from the face to the dump. It is the duty of the designer to give a blaster this leeway, and to provide room and strength in his supports, so that the muck foreman may use heavy machinery to handle these large stones. On Section 13 locomotive cranes and derricks were used successfully at the face, and the supports provided stiffness and strength necessary to load heavy masses at the face by using hoisting engines and lines rigged through blocks fastened to the beam supports overhead.

Even assuming all carefulness on the part of the blaster, a designer will still have to meet, in the deeper cuts, the danger of slides in the face after a blast. This danger is small in shallow cuts, but is a most serious menace in a cut 60 ft. deep. In the side-walls small local slides may be prevented by steel pins or by shoring from the bottom with timber or concrete. Provision against large side slides in deep cuts, in the opinion of the writers, should be made in the

design of the permanent work furnished the contractors. It is a practical impossibility, owing to the numerous fissures and mica seams, to carry along a deep vertical face in New York rock. Careful inspection of the rock at the face, and search for cracks and seams on the top of the rock ahead, will sometimes give warning, but will not take care of a slide when it finally occurs. To meet this danger, the design on Section 13 provided for a span over the face long enough to allow of a support at the toe and one back of the top of the slope formed by a slide. Supports resting on the working face itself were too dangerous and too much in the way to be considered. In the deep cuts the width was so great that a transverse support spanning the cut and resting on the rock at the sides would have been expensive, and would have been useful at one point only, and, owing to the chance of slides, was considered too dangerous. In shallow and narrow cuts a transverse support, of ample strength to carry the street, and of a massive type to resist blasting shocks, was used, and rested well back on the rock at the sides. Sometimes, where the rock was uncertain, an extra support, consisting of a massive built-up post, was placed where it would cause least interference in blasting and excavation. Their size and mass (usually 24 by 36 in.) made these posts safe from chance shocks.

From the standpoint of the man who is actually building the subway, it is usually impracticable to keep the erection of the permanent structure close up to the excavation. The excavation being the largest part of the work of subway building, fast progress necessitates that the system of work shall in no way retard it. If the permanent work follows closely behind the face in a rock cut, it will interfere seriously with excavation, and the excavation will interfere seriously with the permanent work—for instance, interruptions due to blasting. The difference in elevation of the concrete floor and the excavated cut would hinder excavation, and the muck passing through the permanent work would hinder the steel workers, the carpenters, and the concrete men. Thus, the labor cost of both classes of work would increase, and, the progress being slower, the overhead cost would also increase. It has frequently happened in subway construction that the contractor, owing to changes or delays in making the working drawings, has been unable to obtain the materials for the permanent work when needed, and has been forced to keep the excavation

FIG. 3.—A HEAD ROCK RUNNING ACROSS THE CUT.

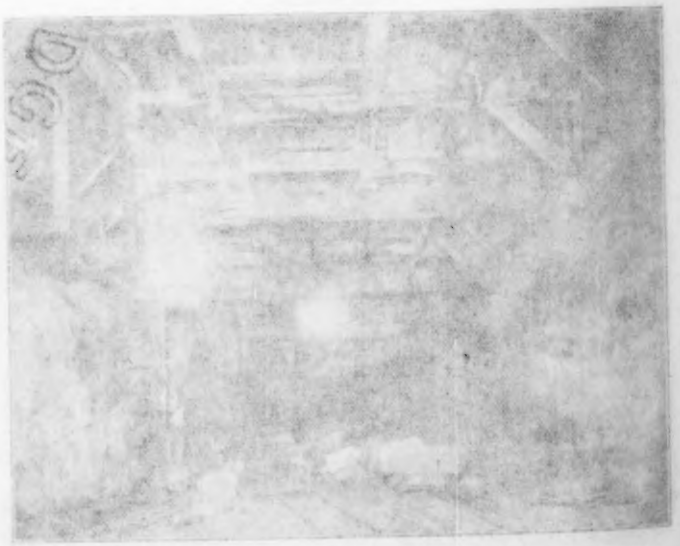
FIG. 8.—METHOD OF TRANSVERSE SUPPORTS UNDER CONTINUOUS BEAMS IN NARROW, SHALLOW CUT.



open at points where he might have placed the permanent work. With the system adopted in Section 13, using steel supports, there could be no deterioration in the main parts to impair materially the safety of the structure.

To carry a 50-ft. length of street on a single span indicates the use of steel. If the designer provides for this span over the face, with good supports at each end, he may have a large factor of safety until one of the supports is shot out, and then he will be left with no factor of safety, and a considerable length of street may drop at once. Complete safety here requires him to have still a factor of safety in reserve by the provision of other supports back of the first ones, so that the breaking of one of these will still leave the structure safe, though that factor will be smaller, owing to the increased span. If bents are used for supports, they should be in pairs, so that one may always be in reserve; and the two bents should be thoroughly braced and tied, forming a tower with a broad base, which cannot be easily overturned. The use of two independent bents, each capable of carrying the load, gives a double factor of safety, and permits of the repairing or shifting of either bent.

To get space and clearance in the cut by combining numerous separate supports into one large one necessitates the use of long-span steel supports between towers. Short spans would not give flexibility enough for the shifting of supports. This point was very important on Section 13, because deeper levels had to be blasted out after the main excavation had been completed, and these extra cuts, sometimes 20 ft. deeper, frequently came directly under the supports. In placing concrete in floors, the extra factor of safety from the use of double bents permitted the contractor to sling to the beams above and then cut off one of the bents, and concrete to the middle of the tower. Then the short bent was wedged on the concrete, and the other bent was cut off, and the concrete placed, thus rendering it unnecessary to leave any posts or holes in the concrete. All needles were placed 10 ft. apart, so that they came exactly between two bents of the permanent steel. A 40-ft. beam was the most convenient length to use, and, as the tower bents came under the needles 10 ft. apart, this left a clear span of 30 ft., the full width of the street, to be carried by the beams with a factor of safety sufficient to allow a 40-ft. span when necessary.

If the beams had rested on bents with broken joints, the towers could not have been shifted, and this and the resulting extra strength led to the use of continuous beams. The beams were used in pairs, spliced at the joint to make a box girder, with long plates on top and bottom flanges and a wooden filler between the webs. To get the extra strength for the span needed over the long working face (55 ft. in the case of Section 13), extra pairs of beams, 100 ft. or more in length, were used on each side of the first pairs and pulled along as the face progressed. The continuous beams were carried in the center of the street, slightly outside the loads from the car tracks. It was necessary to transfer the loads from the driveway and sidewalk to these beams. The main part of the load from the driveway was carried on steel needles the ends of which were cantilevered over from the continuous beams on which they rested.

The load from the sidewalk, which, of course, was much less, was carried on wooden extensions of the steel needles. These extensions were fitted against the web and bolted securely to the steel needle with a long splice, making a joint good for bending, or for compression where it acted as a brace. For facility in posting, and to prevent the needle from rolling, it was packed on both sides with timber so that the whole needle had the shape of a square timber. These wooden plates helped in the placing of the needle by allowing easy fitting at the ends, and also served a valuable purpose, when driving a top lift in rock, in protecting the steel from flying rock while blasting. The needles acted as transverse braces across the cut to keep the whole system rigid, and were wedged against the rock or against the foundation walls of buildings. There were also provided raker struts, from the needles to niches in the rock, which helped to stiffen the structure and minimize vibration. To prevent the continuous beams from rolling, wooden bracing, with heavy turnbuckles on top and bottom of the beams, were put in every 20 ft. between each adjoining pair; similar bracing and buckles were used between adjacent needles.

On Section 13 it was found advantageous to take out a 16-ft. first lift, giving plenty of room for loading muck with machinery. A steel needle has a greater margin of safety than a wooden one at the face, and requires fewer posts. The continuous beams were spliced, and were kept a short distance back as the face advanced, permitting

the use of still fewer posts, thus allowing the placing of tracks and cross-overs where they would most facilitate fast excavation.

As the towers were to carry heavy weights, they had to be well made, and to avoid depending on nails, they were accurately framed, bored, and match-marked in the contractor's yard by a competent foreman, working from a blue-print, and were carefully inspected before being sent to the cut, where the erecting gang put them together on the ground in the bottom of the cut and erected each as a unit. This made a great saving in time and lumber. The employment of high-grade timbermen in the yard and high-grade erectors in the cut specialized the work, and made it economical. The use of a long span over the face permitted a leeway of 2 or 3 days, and the choice of the most favorable opportunity during that time for the erection of the tower. The erecting was usually done at night, in order to prevent any interruption of the excavation during the day, and to permit the erecting gang to work continuously, without stopping for blasts; this also allowed the use of the heavy machinery needed in the day by the excavating gang. It was an important consideration for the contractor to have all possible lumber work done in his yard where he had at hand power tools, such as cranes for lifting heavy sticks, power saws, air augurs, etc. Left-over pieces of timber were valuable for other purposes, but in the cut they were a nuisance, and were wasted. In the yard the foreman had the blacksmith shop near him, the men had places for their tools, and they worked in daylight, without troubling about blasts or workmen over their heads.

As before stated, each tower consisted of two bents, as shown by Fig. 13, and these bents and the bracing between them were all fastened with $\frac{7}{8}$-in. bolts and dock washers. The use of bolts led to simplicity in construction and dismantling, prevented the spoiling of lumber by nails, and left nothing to the discretion of the workmen when assembling the bents. The use of $\frac{7}{8}$-in. bolts, dock washers, and a uniform width of 12 in. for lumber standardized the work, and such standards were maintained throughout the design.

Some of the advantages due to special features of the design described were peculiar to Section 13, but the writers believe that the principle of continuous beams under the car tracks, supporting steel needles carrying the street loads, is necessary in most of the subway rock cuts for safety. The principle offers great advantages

in earth cuts also, because it allows keeping the heavy vertical loads off the cross-bracing, and serves to support the cross-bracing, thus replacing the transverse beams often used across an ordinary earth cut. A great advantage that the continuous beams have here is that they permit of shifting or repairing the cross-bracing without the removal of posts between sets of bracing.

One possible danger which this or any other system of street support and temporary shoring does not, and cannot, cover is the danger to buildings and their occupants along a deep rock cut from a wholesale side-slide where the cut is only about a foot from the building line. Where the danger of a local slide has shown itself in cracks or seams, it has been customary to take care of that particular spot by immediate underpinning, or by putting the building on cantilevered beams (thus taking the weight of the front wall off the edge of the cut), or by shoring of different kinds. There are cases, however, where the rock may be bad and there may be no visible evidence of the fact, as the top of the rock under the building cannot be examined. Up to the present time no general provision for safety from this danger has been made, but, in view of the fact that such a slide may take place, and of the probable large loss of life it might cause, it would seem advisable to provide for the danger, even during the time of construction, by the permanent design. This can be done, without excessive cost, by a perfectly feasible scheme. From the contractor's standpoint in bidding to-day on subways, the smaller the factor of safety the bidder intends to use in his street supporting system, the better his chances of securing the contract.

It would be conducive to greater safety if the main features of the system of support to be used were designed before letting, and bid upon as part of the contract. Systems have been designed piecemeal from the bottom up by combining the ideas of timbermen and other workmen, but the writers believe that the safety of city streets would be better guaranteed with a comprehensive design made by competent engineers. The authority and responsibility connected with the design of street supports, and the inspection of them when placed, or when shifted, or removed, should be in as few hands as possible.

The inspection of the street supports and the rock faces is of the utmost importance in subway excavation. The system which permits

of the most rapid and thorough inspection, with the minimum of necessity for any inspection, will be the least subject to danger, and will cost the least to maintain.

There is no doubt that, with any system of supports, the decking has been and always will be a weak point, owing to the material from which it has to be constructed. It should be made amply strong for the support of the every-day traffic, but it seems unreasonable that a great extra cost, on which the contractor must estimate, should be necessary merely to make the decking safe for an occasional extraordinarily heavy or fast-moving load. In such cases the Fire Department is probably the worst offender. The contractor has no means of defense, unless the City makes the restriction. On Section 13 appeals were made to the Police Department, but it did not have the necessary authority at the time. The contractor placed signs asking that traffic move slowly, hoping for some effect from them. The decking, however, was subjected to some very heavy loads, for instance, a traction engine, a herd of elephants, and a steam shovel weighing more than 20 tons. Such loads are not ordinary traffic, and should be carried on a street without decking. The contractors themselves often use very heavy loads, but they move slowly and are but a slight risk, as they are under control. The comparatively light, fast-moving load is often more dangerous to decking than a heavy, slow-moving one, as it sometimes gets over a point, temporarily dangerous, before it can be stopped. Street-car traffic is so necessary, and so intimately connected with the welfare and convenience of the people, that no provision should be neglected to make it safe and keep it free from interruption. When a danger temporarily comes to the line, however, the street railway company and police should insist on keeping the cars out of such danger, warning of which is given by the contractors' red flags.

The desire to eliminate blasting under a city street has called forth in the technical press discussion of methods of rock excavation without the use of dynamite. Reference has usually been made to the disadvantage of these methods in that they brought out the rock in large pieces. If, however, a machine or a method can be devised to get out the rock from the face as cheaply and as quickly as at present with dynamite, the large-sized pieces would be no objection to its use with a supporting system such as adopted on Section 13.

FIG. 14.—CONTINUOUS BEAMS, WITH CROSS-BRACING AND TURNBUCKLES.

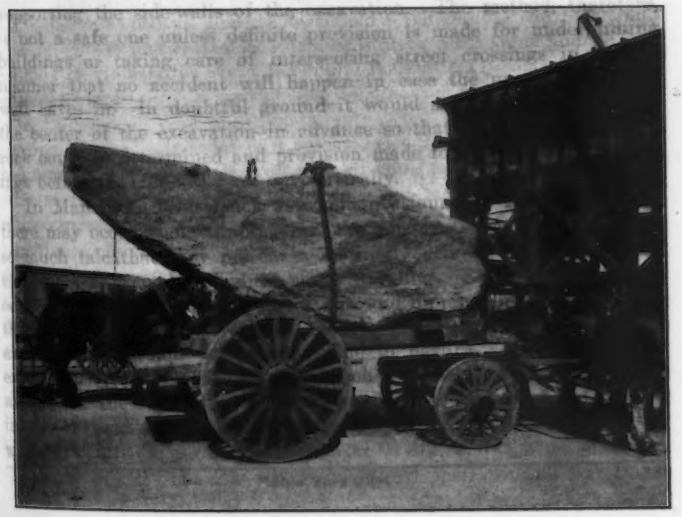

FIG. 15.—25-TON ROCK, HANDLED IN ORDINARY COURSE OF THE DAY'S WORK.

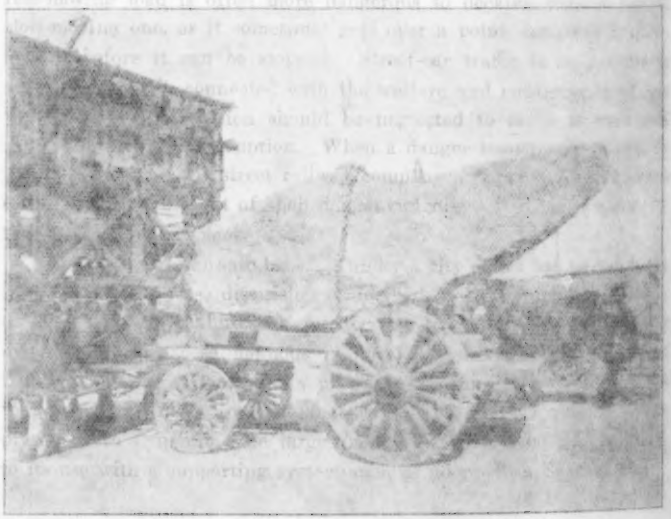

DISCUSSION

Mr. Moulton.

H. G. MOULTON,* ESQ. (by letter).—The method of shoring and street support discussed in this paper is excellent, and fully entitled to classification under the heading "Secure Subway Supports".

The essential feature of safety in this method does not lie in the massive cantilever tower supports in the center, but in the continuous steel longitudinal beams supported thereon. The same ends of safety may be attained—and it is probably open to question as to whether they may or may not be attained at an equal or lower cost—by supporting the continuous beams on transverse girders resting on posts which are in turn securely braced so that they act as retaining timbers for the vertical rock walls of the cut.

Any method of shoring which does not remove the possibility of a sudden local collapse in the side-walls of the excavation is dependent for its safety on continuity of the decking support, so that the decking will carry over if a local rock-fall destroys any one essential supporting member. The same criticism is applicable either to transverse box girders resting on posts adjacent to the walls, or to center supporting towers. In each case any particular support may be destroyed by blasting or by caving of the side of the excavation, and in such an event the entire load of two panels must be transferred immediately, with a fair margin of safety, to adjacent supports.

The method of shoring discussed herein makes no provision for supporting the side-walls of the excavation. The method, therefore, is not a safe one unless definite provision is made for underpinning buildings or taking care of intersecting street crossings in such a manner that no accident will happen in case the unsupported rock wall caves in. In doubtful ground it would seem necessary to open the center of the excavation in advance so that the character of the rock could be determined and provision made for underpinning buildings before the side-walls are cut vertically.

In Manhattan schist such as commonly found in New York City, there may occur seams dipping into the cut at a steep angle, carrying so much talc that they present a distinctly defined plane with practically no frictional resistance against sliding. Should such a seam occur, with a strike parallel to the cut, and dipping in such a manner that it would be cut across or nearly exposed at the bottom of the excavation, it would be quite possible to have a very serious slide extending over a great distance. Such a slide might bring down a number of the supporting towers placed in the center of the cut, as in the method now under discussion, and thereby bring down the whole system.

* New York City.

Mr. Moulton.

In regard to the remarks made by the authors in reference to excessive loads on the decking—that in such cases the Fire Department is probably the worst offender—it has been the writer's general observation that the contractor himself is apt to be the worst offender. With the writer, it has not been an uncommon occurrence to stand at the side of one of the warning signs prohibiting 8-ton trucks from passing, and at the same time observe a contractor's truck, weighing with its load nearer 15 tons than 8 tons, go by at the maximum speed of which it is capable.

The writer takes very decided exception to the authors' main conclusion—that the safety of city streets during subway construction will be better guaranteed if a comprehensive design of the street supports, made by competent engineers, is bid on as a part of each contract. The shoring system in subway excavation is an essential part of the method of construction, and the contractor must devise that system to fit with his usual methods of work and his equipment. It is entirely possible to handle subway excavation safely in a great many different ways. The contractor may use smaller timbers and plenty of them, with good detail, working in small units and keeping his steel structure close to the face. Or he may use large units, so firmly braced that they can stand the shocks of blasting or caves. In this method very great attention must be paid to detail of connections. Or he may provide a continuous decking support which will carry over in the event that he loses any particular point of support. Different contractors have gangs of men trained to timber in certain ways. One firm, for example, has a method of sinking pits down to sub-grade and placing supporting posts therein before excavating the main body of the material. This method might not prove satisfactory to another contracting firm, on account of not having a trained organization used to handling it.

Generally speaking, the contractor who takes the financial responsibility of the work is entitled to do it in any way he chooses, provided he does it in a way that the supervising engineer can accept as safe, from the standpoint of the public. Contractors often develop, under the spur of financial considerations, very interesting, important, and valuable new methods of shoring. For the supervising engineer, or representative of the public, to enter into the field of temporary shoring design would be on his part a trespass on the economic functions of the contractor. The proper function of the supervising engineer ends with designing the permanent work, seeing that it is placed in accordance with specifications, and that while it is being placed the work is done in such a manner that the public safety is properly served.

There are a few points in this paper which are worthy of further mention. The excellent treatment of the I-beams should be noted.

Mr. Moulton.

It will be observed that the beams are in pairs bolted together against a timber filler block, and also that the adjacent pairs are stayed with diagonal braces and steel rods with turnbuckles to resist tension. The steel members, in this manner, should gain stability and resistance against overturning.

In regard to blasting, it seems strange to a mining engineer that this should be considered as so much of a problem in connection with its effects on the shoring structure. In removing ore underground by the square set timber system, where the lower part of the face is advanced ahead of the upper part, it is not uncommon to fire from 40 to 50 shots at a round in a face 50 ft. wide. The holes may be from 2 to 10 ft. from the nearest supporting timbers, and the blast may be heavy enough to break the rock into pieces sufficiently small to be sent down the chutes and trammed out in small cars. The nearest timbers are usually protected by spiking on old planks temporarily. Instead of attempting to keep the timbers sufficiently far from the face to prevent them from being struck by rock from blasts, it is the usual mining practice to design the timbering system in such a way that posts and caps have end bearings to enable them to resist the blows of flying rock; and the connections are also designed in such a manner that the timber system as a whole is not affected if one or two posts or caps should be broken by flying rocks. This point is raised only as an interesting example of the differences in methods developed by subway contractors and mining engineers, which differences, on analysis, would probably prove to be due to material variation in the conditions under which the work is to be carried on, or to the labor and organization available.

Mr. Fiesel.

RICHARD A. FIESEL,* ESQ.—The speaker desires to express his appreciation of this excellent paper. The complexity of the subway structure, the condition of the rock, and the magnitude of the work on Section 13 demanded the attention of intrepid men of sound engineering ability. The structure designed by, and built under the direction of, Messrs. Lueder and Wilson was put to a severe test on one occasion when a blast displaced a tower. The roadway dropped less than 13 in. An examination showed that the superstructure was intact. The adaptability of this structure to the conditions encountered on that part of Section 13 where it was used proved good judgment in its selection.

The speaker is not of the opinion that a comprehensive design of street supports, made by competent engineers, will better guarantee the safety of the city streets, if bid on as a part of each contract, because the shifting of the responsibility for the safety of these structures from the contractor to the City is likely to have an unde-

* New York City.

Mr. Fiesel. sirable effect, and may lead to conditions fraught with danger. The authors' type of structure is a striking example of what the contractors and their engineers are doing to guarantee the safety of the city streets. Knowing that efforts such as these are being made, it would not be wise for the City to launch out on the proposed venture.

There are other considerations: the type of temporary structures used by the contractor for shoring the sides of an excavation, or supporting the roadway, or both, is sometimes an eleventh hour tentative selection. Any type selected must be adapted to the contractor's equipment and method of operation. Sometimes the tentative design is materially modified as a result of studies made as excavation progresses. The contractor may enlarge his equipment or may entirely change his method of operation. The inclusion in the contract of anything affecting this freedom of selection, modification, or operation, would place an unjust burden on the contractor.

A comprehensive design of roadway supports, included in the contract as a separate item, would render the City liable for the safety of the structure, wherefore, in order to protect itself against liabilities arising from possible failures, the City would be compelled to submit designs, similar, in all probability, to those in use to-day, but embodying a factor of safety unwarranted by the conditions encountered, thus adding enormously to the cost of the permanent structure.

Mr. O'Brien. J. H. O'BRIEN,* M. AM. SOC. C. E.—This is a most valuable and timely paper. The speaker, however, is inclined to doubt the practicability and wisdom of the main conclusion if he is correct in understanding that the authors mean to put the design of a scheme of temporary supports wholly on the shoulders of the Public Service Commission.

Under such an arrangement, it is not improbable that one more obstacle would be added for the ingenuity of the expert contractor to overcome in planning the execution of his work.

The scheme would undoubtedly aid an inexperienced contractor, but inexperienced contractors should not be permitted to undertake such work, irrespective of their financial ability.

An engineer charged with the responsibility of awarding contracts in private work would not risk an award to a company, the officers or members of which had had no prior experience in the work.

The speaker recalls an instance where a public commission undertook to design a shut-off dam which formed the basis of part of the contractor's tender.

When the time came to build it, the contractors refused to take the responsibility of carrying out the commission design, and submitted an alternate which was not acceptable to the commission. At the

* New York City.

suggestion of the contractors, an eminent consulting engineer was called in. He prepared a design acceptable to both parties, and it was carried out without difficulty. Mr. O'Brien.

The speaker is fully mindful of the responsibility of the public body in the case of temporary street supports, but is inclined to recommend that it be a mandatory stipulation of contracts for subway work that the contractor shall obtain the formal approval of the commission for a system of supports designed by him, based on specifications defining loading, permissible unit stresses, and other essential restrictions of good design which should be embodied in the specifications of the contract on which he tenders.

B. C. COLLIER,* M. AM. SOC. C. E.—This paper is very pertinent at this time, when the subject of underground railways is being considered in so many sections of this and other cities; and, especially under such conditions, the conclusion reached by the authors warrants the fullest consideration. Mr. Collier.

They have shown that their design of street supports, in rock cuts similar to those found in New York City, is most excellent and one that warrants the fullest consideration for any locality; but it should be borne in mind that a design applicable in one locality may not be utilizable in another, due to sub-surface structures, or for other reasons.

The authors, however, in their main conclusion, call attention to a point which, in the speaker's opinion, is almost axiomatic, in their suggestion that the engineers of the commissions (or other supervising bodies) call for bids based on previously prepared plans for shoring the cuts and supporting the surface. This suggestion will probably be objected to by numerous engineers who will cite that:

First.—It will not allow the contractor the full scope of his ingenuity or the benefit of his experience.

Second.—It will relieve the contractor from his responsibility, and throw the burden on the engineer.

The speaker does not believe that either of these objections (if raised) can stand the "spotlight" of careful analysis. Certainly, no one would do anything to prescribe the ingenuity of the contractor or his engineers, and the speaker cannot see in what way he would be prescribed by having such suggestions made.

The speaker does not go as far as the authors and agree that the engineers should submit a definite plan of shoring, for experience has shown that in most subway cuts each portion of the work is a question unto itself, and one that demands more or less individual treatment; but he believes that suggestions based on careful study of

* New York City.

Mr. Collier.

the situation could be made, which, in themselves, would call for a unit of measurement and a basis for payment. By submitting such proposed plans, and specifying that the contractor might make any modifications or substitutions which would pass the scrutiny and meet the approval of the engineers, the latter would not deny the contractor the benefit of his ingenuity or experience, because he could then compare the proposed scheme with any other he might have in view and govern his bid accordingly, thereby giving him a still further advantage over his less experienced competitor. It must be borne in mind that the preparation of plans, for a work of such large proportions as the usual subway contract, involves the study and thought of numerous men for months, and that the contractor has only a few days in which to analyze the conditions and prepare a bid under which a contract is signed, which contract demands a rigid fulfillment on the contractor's part of all the obligations he has to assume in so doing. The speaker holds, therefore, that anything that can be done by the engineers to prevent the contractor from having to take unusual risks is to the advantage of all parties, and that the establishment of a unit price for such work as "timbering" would be a "long step" toward that end. The engineers would also be directly benefited in that they would have more freedom of action to make such changes or increases as they might feel that the situation demanded, by being able to offer direct compensation to the contractor for doing this work.

It must be borne in mind, also, that all information furnished to the contractor relative to sub-surface conditions is very indefinite; that a plan which might be supposed to govern all conditions would be totally inadequate for the developed conditions; and that any system which demands that the contractor assume all responsibility and financial obligation for this is neither fair nor equitable, and should be changed. The speaker believes that the more closely a specification approximates to a condition under which the risk that a contractor takes is reduced to a minimum, the more satisfactory will be the relationship between the parties working under such specification.

In answer to the second objection, the speaker is of the opinion that, by suggesting or approving a plan for timbering, the engineer does not assume the responsibility. Certainly, no one can infer that the engineer, by withholding such written approval, but still giving his tacit acquiescence, has relieved himself from the obligation that should fall on him, of seeing that the work is carried on in a safe and workmanlike manner. How, then, when a plan which is thought out by both parties, and approved by them, is carried out, will the contractor be relieved from his obligations; for it must be remembered that it is his money which is at stake, and that it is he who must "pay the piper" in case of an accident? Why should it be the policy of an engineer to "hide behind the contractor's skirts", and run to

cover in case of trouble? Accidents will occur, under the most careful supervision, and the more direct the responsibility an engineer is made to feel, the more precaution will be taken; and as the contractor is not made to feel that he has to bear the financial burden of this precaution, he can offer no objection. This brings into consideration another feature suggested by the authors, namely, that of payment for work done outside of neat lines. One of the greatest sources of contention between engineers and contractors on the New York Subway has been the matter of payment for rock excavation beyond the neat lines, and for the concrete which the contractor is required to place to fill such spaces. Of course, it is true that this same subject has been a "bone of contention" on work from time immemorial, and has demanded numerous solutions in various sections, but this in no wise modifies the conditions that exist in New York City, and should be called to the attention of engineers who will perhaps have similar conditions elsewhere. As pointed out by the authors, probably no city in the country is founded on rock of so treacherous a character as New York, and the speaker believes it is inadvisable to provide for payment, other than the usual overbreakage allowances, unless it is thought that there will be slides of a nature similar to those occurring in New York. In such cases, however, he thinks that the specifications should be drawn so as to provide compensation to the contractor for the expense involved under such circumstances by fixing a unit price for payment, which would be large enough to afford a degree of financial relief, but not sufficiently large to create an incentive on the part of the contractor to cause such a condition deliberately. This would be a further advance toward the end desired by the speaker to see specifications drawn so as to reduce the gambling feature of the contract to a minimum. Mr. Collier.

Lazarus White,* Assoc. M. Am. Soc. C. E.—This paper opens up several topics for discussion. Of course, the important thing is always safety—"safety first". The fundamental feature of this paper is that it advocates the design, by the contractor, of a system which will guarantee absolute safety to the public; and, at the same time, other conditions are given. The system, it is stated, must also be economical as regards cost of erection. Is it possible in a system of temporary supports to have absolute safety and economy at the same time? Mr. White.

The usual subway contractor cannot allow much more than $1 per yd. for supports. If he did he would never get a contract, and if he tried to obtain absolute safety, the cost would be prohibitive, as that is something which cannot be realized.

In the speaker's opinion, all that can be done is to adopt a design which has a reasonably safe margin, and then trust to rigid supervision on the part of the engineers and contractors to keep it safe.

* New York City.

Mr. White.

No system of support, however designed, can be safe in itself. It is placed, day and night, by various gangs of timbermen, who have to be trusted to a great extent. They have to work under a series of difficult conditions, at various heights, and on underground structures, all of which require modifications in the supports. No predetermined design could be made to fit these conditions, and, if the contractors tried to make a rigid design, they would get into trouble.

The next point is the supposition that, if the timbering were designed in advance by the engineers who prepare the contract, that is, the engineers of the public service commission, greater safety—the speaker will not say "absolute safety"—could be secured, and the contractors would be bidding on the same basis; but, the speaker agrees with most of those who have discussed this matter, that this would not be desirable.

These contracts are prepared in great haste, and the commission engineers have not the time to design these timbering systems to meet the varying conditions of the different contracts; and if they were designed, the speaker does not believe that the contractor could follow them absolutely, at least, he would ask for changes, and then he would have the responsibility.

As a matter of fact—the speaker does not know whether it is intended—it seems to be an inference that the timber systems used in other structures have been erected by carpenters and various foremen. The speaker knows that such is not the case. For the last 10 or 15 years most of the contractors have had engineers, and very competent ones—members of this Society—who have designed their timber systems and looked after them. Thus, most of the timber systems were designed by competent engineers; and it makes very little difference whether they were or were not in the employ of the State.

The paper lays great emphasis on the benefit of getting out rock in large sizes, as this is considered to be safer and more economical. On that point there is a fair difference of opinion. The firm with which the speaker is connected put in bids on most of the main subway contracts, and examined the various methods of rock excavation, visiting most of the places where work was under way. The impression gained was that in those cases where it had been planned to break up the rock into small pieces (about two-man size) the material was being handled more expeditiously, and more economically than those which handled the rock in large sizes. Although the speaker's firm is at work on only one subway contract which has no rock excavation, its members have been in charge of rock excavation and open-cut aqueduct and tunnel excavation, and therefore may fairly claim to be familiar with rock excavation methods.

To handle large rocks requires very large appliances, and there is always a risk of break-downs. There is no difficulty in breaking

up large rocks in the cut. With rotating drills they are very easily drilled, and then can be shot, either with the main shots or at other times. Mr. White.

The paper states that the rock shown on a truck, in Fig. 15, weighs 25 tons, but a calculation seems to indicate that it could not have weighed more than 10 tons.

The speaker believes that the most valuable part of the paper is that which deals with longitudinal supports. In that he agrees with the authors. Such supports are of enormous value in subway construction, in safeguarding it to a very large extent, and they introduce a great element of flexibility; but they are not by any means new, or peculiar to this one job, for they have been used for the last 10 years or longer, and, in fact, patents have been granted for supports of this type.

In the speaker's work he has also used longitudinal supports in the timber system, but they are quite different from those described in the paper. Longitudinal supports are all right, but it cannot be said that entire reliance can be placed on them, because the intersection of the cut is left unprotected. There is a street crossing about every 200 ft., and this requires as much support as the main street, because there are found pipes, conduits, etc.; so that, for these places at least, transverse supports are necessary.

Rock slides are a great element of danger, but there is something peculiar about a rock slide, it sometimes requires very little support to prevent it. A slight transverse support might prevent it from sliding. There is an enormous difference between nothing and some support.

A point is made of the fact of the permanency of steel compared with timber. It is hard to conceive of a timber system that would not last the length of a subway job without deteriorating; otherwise it would be unfit for use in the first instance.

The authors express the hope that blasting may be eliminated, as being a source of danger. It is a source of danger, of course, but there is about as much chance of eliminating blasting from subway rock work as of eliminating powder from war.

A. B. Lueder,* M. Am. Soc. C. E., and W. J. R. Wilson,† Esq. (by letter).—The writers are much gratified by the interest and appreciation with which this paper has been received and by the discussions. They do not concur with some ideas brought out by the discussion which do not concern street supports directly. Messrs. Lueder and Wilson.

Referring to Mr. Moulton's remarks, the writers are pleased with his general approval of the paper and interested in the point of view of a mining man, although they believe that the general practice of excavating rock in a mine is not applicable to subway excavation.

* Morristown, N. J.
† Brooklyn, N. Y.

Messrs. Lueder and Wilson.

The paper was presented in order to illustrate a method of street support which had been used successfully and had fulfilled the conditions which it was designed to meet. The writers stated expressly that this system was not designed to take care of possible slides in the side, but so that the street supports would not be endangered by a side slide or by blasting. On Section 13 side slides were not always taken care of as it is believed they should have been, but every effort was made to eliminate them by careful supervision of the timbering and blasting. Their danger was minimized by carrying the underpinning to solid rock which had no tendency to slide, or by cantilevering the buildings off rock which was likely to slide, while depending on the tower supports in the center of the cut and the continuous beams to support the street.

The writers think that the question of extensive side slides should be considered in the design of the permanent work. They believe that, as a prime consideration of design, the street supports should be made safe. Any system of street support which depends on the stability of rock in the sides presents a great element of danger. Transverse supports cannot be put in until excavation is made. If such supports were used, the same street loads (in such a case as on Section 13 with a transverse width of 60 ft.) would have to be carried on longer spans than if the spans were longitudinal. The supports on the unstable sides of the cut would be unsafe, but those actually used rested on the bottom in the center of the cut, and were obviously on safe rock. Where the cut was narrow, transverse supports were used, but the street was still supported on continuous longitudinal beams.

The question of side slides and the danger therefrom will always be pertinent to the subject of subway excavation in New York City, but it would seem to be good practice to take the street support design out of the realm of this danger, and the writers treated the subject in this way. The extensive side slide which would bring danger to the system, as used on Section 13, would carry away with it buildings and any transverse system possible on that section. A fairly large side slide that did occur left the street supporting system unaffected. In a wide cut, such as on Section 13, the houses are practically on the edge of the cut; they will be in danger before any system of timbering can be put in, and necessarily must be taken care of first. This was done by underpinning carried to rock which investigation showed to be sound and without seams. This method of underpinning is expensive to the city, and any method of permanent construction which would guarantee safety of all side-walls would eliminate much of the underpinning cost.

There seems to be no pertinency in Mr. Moulton's suggestions as to the use of a mining system in which the lower part of the face is

Messrs. Lueder and Wilson.

kept in advance of the upper part. This would do in a tunnel, but not when there is a street overhead. It is generally agreed by experienced engineers that the open quarry method is, on the whole, the cheapest yet devised for rock cuts, and ideal subway excavation approaches that method. The writers believe that in the present system of subway building, the design of the permanent work and the shoring methods used by the contractors do not provide thoroughly against the wholesale side-slide danger referred to in the discussions. They think, however, that under the present method of bidding, the contractor is not justified in providing for such a contingency. Luckily, there has not yet been such a slide, but any engineer who has actually supervised subway construction in deep rock cuts in New York City realizes that there is a possibility that it will occur. If it does, it will certainly mean the destruction of buildings and probably great loss of life. There would follow investigations and undoubtedly mandatory legislation compelling the supervising authorities to adopt measures for absolute safety. If such measures were framed by lawyers and politicians, it might greatly increase the cost of subway building. The contractor cannot be expected, as before stated, to adopt a fixed system of supporting the side rock, whether or not it appears to be dangerous, and no amount of supervision will stop a slide, or always foresee it; but the writers believe that the design of permanent work can be modified so that it can be made to take care of any possibility of an extensive slide, and at the same time give the contractor ample opportunity to use up-to-date methods for fast excavation and construction.

The City, of course, pays for the design and the erection of the contractor's temporary supports, and also for the final permanent construction. There seems to be no reason why a permanent design should not provide more flexibility and, to a large extent, be made to take the place of a contractor's temporary system. By being designed beforehand and bid on as part of the contract, it would provide safety to the public.

The writers admit that the contractor's loads are heavy, but they are under his control, and they certainly do not overrun red flags. Mr. Moulton's reference to excavation in pits—which is a soft ground proposition—would not apply of course to a rock section. In subway work workmen are trained in their especial trades as blasters, carpenters, etc., and it is the man who uses them who needs to be experienced. As has been stated, the writers do not consider it a safe system to allow workmen to build up a patch-work design; it should not be changeable at their whims.

Referring to Mr. Fiesel's remarks, that a comprehensive design of temporary roadway supports would add enormously to the cost of the permanent structure, does not the present form of contract pay the

Messrs. Lueder and Wilson.

contractor for just such a design, and is it not the office of the Public Service Commission to see that he uses a safe design? In their experience with the Public Service Commission the writers certainly found no desire to allow a contractor to make money at the expense of public safety. The point is, though, and to that extent the writers thoroughly agree with Mr. Fiesel, that the City will have to pay a great deal more for its subway construction, if it has to pay for doing the same thing twice. That is one reason they advocate the inclusion, in the design of the permanent work, of features enabling it to fulfill for the contractor the purpose of a thoroughly safe side-wall and street-supporting system on which to bid. The writers do not intend to say that the City should design an elaborate temporary structure for the contractor, apart and separate from the design of the permanent work. They had in mind a method of construction which might have been used on Section 13, which would have provided against the danger of side slides, and have also largely answered the purpose of the street-supporting system used. This scheme, however, would have had to be part of the permanent work; the contractor could not use it separately. If, though, it had been part of the contract, it would have eliminated completely any chance of large scale disaster due to the erection of an imperfect temporary system by a contractor. The paper did not bring out very clearly the exact idea of the writers in advocating pre-designed street supports. They agree, to a certain extent, with those who discussed it, in believing that it would not be advisable to have a rigid system of temporary shoring designed by the Public Service Commission and incorporated in the contract. The public, however, should be secured by the design on which the contractor bids, as brought out by Mr. O'Brien. There is no question in the mind of any engineer experienced in subway rock work that there is a possible danger from an extensive rock slide, as referred to by Messrs. Moulton and Collier.

It is believed that the present permanent design of the subway can be modified so that it will provide against any large side slide, take the place of much of the contractor's present temporary system, and yet not add to the cost of the work to the City. With such a design, the permanent work will cost probably more for the materials used, but it will insure safety, and will make excavation and underpinning costs much less. Every contractor then would be able to figure more closely, and would have to figure on doing the work safely, because the design would provide for his doing so, and it would also provide ample leeway for ingenuity in the methods used and leave him free in his own sphere.

Mr. Collier's reference to payment for excavation beyond the neat lines for rock and concrete will interest all contractors.

Paper No. 1366

CHEMI-HYDROMETRY AND ITS APPLICATION TO THE PRECISE TESTING OF HYDRO-ELECTRIC GENERATORS*

By Benjamin F. Groat, M. Am. Soc. C. E.

With Discussion by Messrs. G. Bertram Kershaw, George W. Fuller, W. D. Peaslee, W. L. Waters, Robert E. Horton, Thomas H. Wiggin, W. S. Richmond, and Benjamin F. Groat.

Synopsis.

This paper is divided into five parts. A summary of each part (except Part IV) will be found on pages 955, 1006, 1136, and 1231.

Chemi-hydrometry, more explicitly defined in Section 6, relates to the measurement of quantities of fluids by chemical methods.

Introduction.

Owing to the large bonus and liquidated damages clauses of the contract considered in this paper, it was apparent that unusual precision was necessary in executing the tests to determine the performance and efficiency of the new hydro-electric equipment. Besides this, there were other equally cogent reasons for making the tests as precise as possible with such methods as sound engineering practice and field methods could furnish. Among these may be mentioned the strong probability of large future purchases of hydro-electric equipment, and the concomitant necessity for accurate methods of testing, coupled with the fact that there had not yet been developed

* Presented at the meeting of December 15th, 1915.

any method for measuring the volume of large quantities of turbulently flowing water, which would furnish convincing results reliable to within 1% of the true quantity.

The uncertainty attending the measurement of large volumes of flowing water by methods heretofore used, under the most favorable circumstances and according to the best information at hand, is about as follows:

Moving screen.....	½ to 1%
Weirs	1%
Current meters.....	2 to 8%, and even higher.

The last case supposes that the meters have been rated in the usual manner in still water, and that this rating is presumed to remain unchanged during the measurements. Current meters under these circumstances have been known by the writer to be in error by more than 100% of the true velocity.

So far as the writer is aware, his tests of turbines in 1911* were the first in which any attempt was ever made to correct the still-water ratings of current meters. During these tests it was shown that screw meters under-register and cup meters over-register, and the discrepancy thus arising was found to be 8% as an average, the particular types of meter involved being the larger sizes of the Haskell and Price patterns. At certain points in the races corrections exceeding 15% were found to be necessary.

In view of these facts, and the fact that the contract under consideration specified the Haskell meter as one of the instruments for testing, it was decided to use the chemical method in parallel with three types of meter: the Haskell, Ott, and small Price. The Ott meter is of the screw type, and the small Price is a more accurate instrument than the larger type.

Ratings of all the meters were made at the Naval Tank at the University of Michigan, and curves were constructed showing the relative divergences of the ratings for given amounts of oscillation which were supposed to represent disturbance or "turbulence" of flow. Both transverse and longitudinal oscillations, with reference to the direction of motion of the meters, or water, were studied.

The results of the subsequent tests on the Allis-Chalmers equipment in the summer of 1914 confirm the conclusions drawn from the

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 819.

tests of 1911 concerning current meters, and the chemical tests, which are hereafter shown to be accurate to a fraction of 1%, prove conclusively that current-meter work in perturbed water must include corrections to be applied to the still-water rating, if accurate results are to be exacted. They also show that the methods of correcting the meter records used by the writer in 1914 are sufficiently accurate to secure results within 1 or 2%, even where corrections of 15%, or more, must be applied to records based on still-water ratings.

The chemical method had never been used in measuring large quantities of water with precision, the quantities dealt with usually being limited to a few cubic feet per second in the case of high-head plants where the turbines were fed by pipe lines. Somewhat larger volumes had been measured by Dr. Leon W. Collet, in the case of Swiss mountain torrents, and Stromeyer, in England, had measured boiler feed and some small streams at even earlier dates.

After reviewing these experiments, a plan was devised for testing large-capacity turbine units where discharges of several thousand cubic feet per second could be measured with precision. In devising this plan, the very accurate method of Dr. R. Mellet, of the University of Lausanne, Switzerland, for performing high-precision titrations was adopted, but it was found on trial that the method of unbalanced evaporations for conducting the remainder of the tests introduced a systematic error of greater or less degree, the magnitude of which in the present series of tests was about $\frac{1}{4}$ of 1 per cent.

The writer was not enthusiastic over the chemical method until he read Dr. Mellet's extremely valuable paper, presenting the basis for these exceedingly accurate titrations, and demonstrating clearly what degree of accuracy can be secured by such a procedure. Even then it was questionable as to how applicable the method would be to turbines of large capacity operating on low heads with correspondingly large discharges. The very satisfactory tests cited by Dr. Mellet, where the discharge of the Day power-plant at Vallorbe was accurately determined, would scarcely give any idea of the possible precision attainable in the proposed tests, because the discharge measured at Vallorbe was only 262 liters per sec., whereas it would now be necessary to measure 50 000 liters per sec. with all possible precision.

Especially was there much doubt as to the uniformity of mixture which could be secured, and as to the method of introducing the

chemical into the head-race. The methods of sampling were also to be determined, as well as the size of the solution tank and the proportions of the other parts of the testing equipment.

After some further study of actual tests, it was found that the method suggested by the writer in a paper which he presented before the Engineers' Society of Western Pennsylvania in December, 1913, eliminated the error above mentioned, along with a number of other errors, and that, in fact, it supplies all the elements of precision necessary for the most refined work. The formula which indicates the methods first appears in a somewhat more complicated form than necessary.* These methods have since been applied successfully by the writer in several tests in different parts of the country.

In order to show that turbine testing has been anything but an exact science in the past, it may be stated that there have been several extensive series of tests which can be regarded in no other light than as failures, in so far as decisively definite results are concerned, and that in at least one case, after an expenditure of many thousands of dollars, there was an uncertainty as to the resulting efficiency amounting to 3 per cent. Current meters were used in that test.

Turbine testing and discharge gauging have been more of an art than a science. Results have depended more for accuracy on the particular person who directed the work than on any method heretofore used. It has been a common occurrence that there has been a complete failure to interpret the data correctly, with the result that much of the work in discharge measurements has been unsatisfactory. When results have been shown to be accurate, we may rest assured that the person conducting the tests has arrived at a conclusion only by the most painstaking efforts and perseverance.

The results of the studies mentioned will be treated in five parts:

I.—History and Theory;
II.—Errors;
III.—Description of Testing Plant;
IV.—The Tests;
V.—Current Meters.

A brief summary is given at the beginning of each part.

* *Proceedings*, Engineers' Society of Western Pennsylvania, May, 1914, Vol. 30, p. 374.

PART I.

HISTORY AND THEORY.

SUMMARY.

1.—In Part I a complete theory of mixtures of salt solutions of various densities has been evolved and elaborated into a comprehensive treatise on the subject. This includes tables and diagrams of properties of the salt solution. This theory is necessary for high-precision work on account of the shrinkage in volume which takes place when two or more different salt solutions are mixed.

The term "Chemi-hydrometry" has been proposed as the name for this new branch of engineering science.

The reader's attention is called to the important fact that there is great advantage to be gained by measuring quantities of the solutions by weight rather than by volume. This eliminates in large measure the necessity for observing the temperatures of the solutions and making the corrections therefor. There is further gain in accuracy due to the fact that there is less likelihood of contaminating the samples by reason of neglect to clean the thermometer each time before it is dipped into a sample or other solution. Moreover, this method gives the real quantity which is desired in turbine testing, namely, the weight of the water passing through the water-wheels as against the volume.

A complete method has been devised for the precise testing of hydro-electric units of large capacity with a chemical injected into and mixed with the feed-water. This method is based on the original suggestion by Schloesing in France, in 1863, the method of precise titrations of weak salt solutions devised by Dr. R. Mellet, and the design and operation of chemical testing plants, as suggested in a paper by the writer before the Engineers' Society of Western Pennsylvania in December, 1913.* This paper also contains the formula which leads to the method of balanced evaporations, accomplished by special dilutions in the laboratory.

The formula for balanced evaporations is treated in full, as it applies to tests under various conditions. It leads to the elimination of all uncertainty as to the properties of the normal head-water. It indi-

* *Proceedings*, Engineers' Society of Western Pennsylvania, May, 1914.

cates and represents a definite laboratory procedure which has been outlined in accordance therewith.

The coefficient of shrinkage of volume, when two salt solutions are mixed, has been fully treated and tabulated.
